Primary members or components, or portions thereof, subject to a net tensile stress under Strength Load Combination I shall be designated on the contract plans. Unless otherwise indicated on the contract plans, Charpy V-notch testing shall be required for primary members or components that are subject to a net tensile stress, or for portions thereof located in designated tension zones, under Strength Load Combination I, except for diaphragm and cross-frame members and mechanically fastened or welded cross-frame gusset plates in horizontally curved bridges.

their components have special requirements in the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code* for magnetic particle testing. In addition, for complete joint penetration groove welds in primary members, the type and frequency of radiographic or ultrasonic testing depends on whether the component is subject to tension or compression, and the acceptance criteria are different. Certain fabrication methods, such as punching holes full size, are limited to certain secondary and primary members according to Article 17.1.2 of the AASHTO *LRFD Steel Bridge Fabrication Specifications*.

Therefore, Article 6.6.2.1 requires that primary members or components, or portions thereof, subject to a net tensile stress under Strength Load Combination I be designated on the contract plans. Designation of secondary members or components, as listed in Table 6.6.2.1-1, as primary members or components should be carefully scrutinized as this will invoke more costly and complex fabrication and testing requirements that do not add significant value and are not necessary. Secondary members or components that are specifically designated as primary members or components by the Owner should be indicated as such on the contract plans, and also whether or not those members or components, or portions thereof, are subject to a net tensile stress under Strength Load Combination I.

Cross-frame and diaphragm members in straight and horizontally curved composite box-girder bridges are treated separately in Table C6.6.2.1-1 as these members do not necessarily serve the exact same functions as in I-girder bridges. Intermediate internal diaphragms that are provided for continuity and their associated intermediate external diaphragms are to be designated as primary members. An example might be where such diaphragms are utilized in a straight or horizontally curved twin-tub girder system with the tub girders classified as SRMs. External support diaphragms or cross-frame members in all composite box-girder bridges are to be designated as primary members because they are necessary to support the deck and the live loads and restrain the rotation of the boxes to provide torsional stability. In some cases, such as when single bearings are used under the boxes, these members must also be designed to distribute significant box girder torsional moments as vertical force couples between adjacent girder bearings. Internal support diaphragms in straight box-girder bridges with skewed supports or in horizontally curved box-girder bridges not satisfying one or more of the conditions specified in Article 4.6.1.2.4c for neglecting the effects of curvature are to be designated as primary members because they are considered to perform a necessary load path function in these bridges by resisting the shear and bending caused by significant torsional moments at the supports. Finally, intermediate external diaphragms that are provided in all composite box-girder bridges with concrete decks designed using the empirical design method to satisfy the design conditions specified in Article 9.7.2.4 are also to be designated as primary members as they are necessary

to control the differential displacements between the boxes to ensure that the resulting moments that are generated over the webs do not require any additional reinforcing in the deck. Otherwise, these members are to be designated as secondary members as described further in Table 6.6.2.1-1.

Table 6.6.2.1-1 is not necessarily all-inclusive and the designation of any members or components that are not listed in the table is subject to the judgment of the Engineer.

Specifying that Charpy V-notch testing be performed for members, components, or portions thereof for which such testing is not required according to the provisions specified herein, e.g., secondary members, adds additional complexity and cost without providing any significant additional value. Designation of entire members or components as subject to a net tensile stress, rather than merely their tension zones where applicable, also adds unnecessary cost and is inconsistent with the objectives of the fracture control plan specified in the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*. Although classified as primary members, some cross-frames and diaphragms and their components in curved bridges have become subject to Charpy V-notch testing requirements, yet in many years of practice, no specific concerns related to the fatigue and fracture performance of these members have been demonstrated.

Table 6.6.2.1-1—Member or Component Designations

Member or Component Description	Member or Component Designation
Girders, beams, stringers, floorbeams, bent caps, and bulkheads	Primary
Truss chords, diagonals, verticals, and portal and sway bracing members	Primary
Arch ribs and built-up or welded tie girders	Primary
Rigid frames	Primary
Gusset plates and splice plates in trusses, arch ribs, tie girders, and rigid frames	Primary
Splice plates and cover plates in girders, beams, stringers, floorbeams, and bent caps	Primary
Bracing members supporting arch ribs	Primary
Permanent bottom-flange lateral bracing members and mechanically fastened or welded bottom-flange lateral connection plates in straight and horizontally curved bridges	Primary
Top-flange lateral bracing members or struts and top-flange lateral connection plates in straight and horizontally curved bridges	Secondary
Diaphragm and cross-frame members and mechanically fastened or welded cross-frame gusset plates in straight I-girder bridges with or without skewed supports, and in horizontally curved I-girder bridges satisfying all the conditions specified in Article 4.6.1.2.4b for neglecting the effects of curvature	Secondary
Diaphragm and cross-frame members and mechanically fastened or welded cross-frame gusset plates in horizontally curved I-girder bridges not satisfying one or more of the conditions specified in Article 4.6.1.2.4b for neglecting the effects of curvature	Primary
For composite box-girder bridges: • Intermediate internal cross-frame members and their mechanically fastened or welded gusset plates; • Intermediate internal diaphragms that are not provided for continuity; • Except as specified herein, intermediate external diaphragms or cross-frame members and mechanically fastened or welded intermediate external cross-frame gusset plates; and • Internal support diaphragms in straight bridges without skewed supports or in in horizontally curved bridges satisfying all the conditions specified in Article 4.6.1.2.4c for neglecting the effects of curvature	Secondary

Table 6.6.2.1-1, (cont.)—Member or Component Designations

For composite box-girder bridges: • Intermediate internal diaphragms that are provided for continuity and their associated intermediate external diaphragms; • External support diaphragms or cross-frame members and mechanically fastened or welded external support cross-frame gusset plates; • Internal support diaphragms in straight bridges with skewed supports or in horizontally curved bridges not satisfying one or more of the conditions specified in Article 4.6.1.2.4c for neglecting the effects of curvature; and • Intermediate external diaphragms provided in bridges with concrete decks designed using the empirical design method to satisfy the design conditions specified in Article 9.7.2.4.	Primary
Diaphragm and cross-frame members, and mechanically fastened or welded cross-frame gusset plates and bearing stiffeners at supports in bridges located in Seismic Zones 3 or 4	Primary
Bearings, filler plates, sole plates, and masonry plates	Secondary
Mechanically fastened or welded longitudinal web and flange stiffeners	Primary
Mechanically fastened or welded transverse intermediate web stiffeners, transverse flange stiffeners, bearing stiffeners, and transverse connection plates	Secondary
Mechanically fastened or welded batten plates and stay plates, lacing, and continuous nonperforated or perforated plates in built-up members	Primary
Eyebars and hanger plates	Primary
Miscellaneous structural components or attachments not mentioned above joining two primary members	Primary
Miscellaneous nonstructural components or attachments (e.g., expansion dams, drainage material, brackets, other miscellaneous attachments)	Secondary

Charpy V-notch impact energy requirements shall be in accordance with AASHTO M 270M/M 270 (ASTM A709/A709M) for the specified temperature zone.

The appropriate temperature zone for the Charpy V-notch requirements shall be determined from the applicable minimum service temperature specified in Table 6.6.2.1-2, and shall be designated in the contract documents.

Table 6.6.2.1-2—Temperature Zone Designations for Charpy V-notch Requirements

Minimum Service Temperature	Temperature Zone
0°F and above	1
–1°F to –30°F	2
–31°F to –60°F	3

The Charpy V-notch impact energy requirements, specified in AASHTO M 270M/M 270 (ASTM A709/A709M) and shown in Table C6.6.2.1-1, vary depending on the grade of steel, and the applicable minimum service temperature. The basis and philosophy of these impact energy requirements is given in AISI (1975).

NSTMs, newly designed SRMs, and primary plate components in newly designed IRMs require fracture control (FC) practice as specified in Article 6.6.2.2, and are therefore subject to more stringent Charpy V-notch impact energy requirements than load path redundant members (LPRMs). For flexural members, FC practice only applies in portions of the member located in the designated tension zones under Strength Load Combination I where these classifications apply.

Steel grades for LPRMs in tension or the designated tension zones on LPRMs subject to Charpy V-notch testing as specified herein are designated with the suffix “T” in AASHTO M 270M/M 270 (ASTM A709/A709M). Steel grades for members or designated tension zones requiring FC practice and subject to more stringent Charpy V-notch testing are designated with the suffix “F” in AASHTO M 270M/M 270 (ASTM A709/A709M), as shown in Table C6.6.2.1-1. The “T” and “F” designations are for the use of the mill and the Fabricator only and need not be shown on the contract plans.

Table C6.6.2.1-1—Charpy V-Notch Impact Energy Requirements

Grade (Y.P./Y.S.)	Thickness (in.)	Members or Designated Tension Zones Requiring FC Practice Designated as “F”				LPRMs in Tension or Designated Tension Zones on LPRMs Designated as “T”		
		Min. Test Value Energy (ft-lbf.)	Zone 1 (ft-lbf. @ °F)	Zone 2 (ft-lbf. @ °F)	Zone 3 (ft-lbf. @ °F)	Zone 1 (ft-lbf. @ °F)	Zone 2 (ft-lbf. @ °F)	Zone 3 (ft-lbf. @ °F)
36	$t \leq 4$	20	25 @ 70	25 @ 40	25 @ 10	15 @ 70	15 @ 40	15 @ 10
50/50S/50W	$t \leq 2$	20	25 @ 70	25 @ 40	25 @ 10	15 @ 70	15 @ 40	15 @ 10
	$2 < t \leq 4$	24	30 @ 70	30 @ 40	30 @ 10	20 @ 70	20 @ 40	20 @ 10

HPS 70W	$t \leq 4$	28	35 @ –10	35 @ –10	35 @ –10	25 @ –10	25 @ –10	25 @ –10
HPS 100W	$t \leq 2\frac{1}{2}$	28	35 @ –30	35 @ –30	35 @ –30	25 @ –30	25 @ –30	25 @ –30
	$2\frac{1}{2} < t \leq 4$	not applicable	not permitted	not permitted	not permitted	35 @ –30	35 @ –30	35 @ –30

6.6.2.2—NSTMs

The Engineer shall classify primary steel members fully or partially in tension that are without load path redundancy, system redundancy, or internal redundancy as NSTMs. For flexural members, only the portions of the member located in designated tension zones under Strength Load Combination I shall be classified as an

C6.6.2.2

In most cases, load path redundancy can be determined by engineering judgment or simple calculation. Examples include parallel beams or girders with similar stiffness in common composite beam-slab bridges with four or more girders for all spacings, or with three beams or girders at spacings not exceeding 16.0 ft.

NSTM. Such members or the portions of a flexural member located in the designated tension zones, as applicable, shall be identified on the contract plans as an NSTM. FC practice shall apply for NSTMs.

Any attachment, except for bearing sole plates, having a length in the direction of the tension stress greater than 4.0 in. that is welded to a tension area of a component or member without load path redundancy, shall be considered part of the tension component or member and shall be classified as an NSTM subject to FC practice.

The Engineer may classify primary steel members fully or partially in tension that are without load path redundancy, but have system or internal redundancy, as SRMs or IRMs for in-service inspection per 23 CFR 650.313(f)(1)(i) with FHWA-approved procedures in conformance with a nationally recognized method. These members shall be identified on the contract plans as a SRM or an IRM, as applicable; for flexural members, only the portions of the member located in the designated tension zones should be identified as such. FC practice shall apply for newly designed SRMs and primary plate components in newly designed IRMs, or for the portions of a flexural member located in the designated tension zones where these classifications apply.

Members classified as NSTMs must be primary steel members, except as noted below, must be fully or partially in tension, and must lack load path redundancy, system redundancy, or internal redundancy. NSTMs are to have routine inspections performed, along with hands-on in-service inspections as described in 23 CFR 650.

The *National Bridge Inspection Standards* (NBIS) were revised in May 2022 and eliminated the term “fracture critical member” (FCM) in favor of the term NSTM because of its implicitly negative connotation and because it was frequently misunderstood by those that did not work regularly with the NBIS. Until such time as other specifications are revised, for consistency, the terms FCM and NSTM are to be considered synonymous. Also, the term “LPRM” is to be considered synonymous with the term nonfracture-critical member.

The 2022 NBIS also recognized SRMs and IRMs for purposes of alleviating NSTMs from in-service NSTM inspection. The NBIS defines the conditions under which NSTMs may be reclassified as SRMs or IRMs. Per an FHWA memo (FHWA Memorandum, May 9, 2022), the *AASHTO Guide Specifications for Analysis and Identification of Fracture Critical Members and System Redundant Members* and *AASHTO Guide Specifications for Internal Redundancy of Mechanically-Fastened Built-Up Steel Members*, or an alternative method satisfying either of the two criteria specified in 23 CFR 650.313(f)(1)(i)(B), are considered nationally recognized methods to determine SRMs or IRMs.

Secondary members and primary diaphragm or cross-frame members in horizontally curved bridges should not be classified as NSTMs, SRMs, or IRMs.

FC practice is required for materials and fabrication of NSTMs, newly designed SRMs, and primary plate components in newly designed IRMs. FC practice should not be required for LPRMs. For materials, FC practice requirements include the more stringent Charpy V-Notch impact energy requirements designated as “F” in AASHTO M 270M/M 270 (ASTM A709/A709M), as shown in Table C6.6.2.1-1. For fabrication, when welding is required, FC practice requirements include those found in AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*, Clause 8.19.8 and Clause 12, the *AASHTO LRFD Steel Bridge Fabrication Specifications*, and any other Owner-specified requirements.

The Engineer need only identify NSTMs, SRMs, and IRMs on the contract plans where these classifications apply; all other primary members or portions of primary members are LPRMs by default and need not be identified as LPRMs on the contract plans. The designation “FC” and identification of the specific FC practice requirements for these members, or portions thereof, is not necessary on the contract plans and should be avoided. Fabricators will use the term “Fracture Control Practice” or the designation “FC” on shop drawings to identify the need for the FC practice requirements.

The exclusion of bearing sole plates from NSTM classification is because they are located in regions of low or zero tensile stress at the ends of spans or in regions of compression at interior supports of continuous spans. Preheating to fracture-critical temperatures may also be harmful to some bearing materials. Bearings and sole plates are also designated as secondary members in Table 6.6.2.1-1, exempt from NSTM classification.

6.7—GENERAL DIMENSION AND DETAIL REQUIREMENTS

6.7.1—Effective Length of Span

Span lengths shall be taken as the distance between centers of bearings or other points of support.

6.7.2—Dead Load Camber and Detailing of Structural Components

Steel structures should be cambered during fabrication to compensate for dead load deflection and vertical alignment.

Deflection due to steel weight and concrete weight shall be reported separately. Deflections due to future wearing surfaces or other loads not applied at the time of construction shall be reported separately.

Vertical camber shall be specified to account for the computed dead load deflection.

When staged deck placement or phased construction is specified, the sequence of load application and the change in the composite stiffness during the different stages of the deck placement shall be considered when establishing girder cambers.

Selective changes to component length, as appropriate, may be used for truss, arch, and cable-stayed systems to:

- adjust the dead load deflection to comply with the final geometric position,
- reduce or eliminate rib shortening, and
- adjust the dead load moment diagram in indeterminate structures.

The contract documents should state the fit condition for which the cross-frames or diaphragms are to be detailed for the following I-girder bridges:

- straight bridges where one or more support lines are skewed more than 20 degrees from normal;
- horizontally curved bridges where one or more support lines are skewed more than 20 degrees from normal and with an L/R in all spans less than or equal to 0.03; and
- horizontally curved bridges with or without skewed supports and with a maximum L/R greater than 0.03.

C6.7.2

Article 6.7.2 requires that, generally, the effects of staged deck placement as well as the impact of phased construction are to be considered when establishing girder cambers. In addition, these effects are an important consideration subsequently in setting screed requirements for construction. AASHTO/NSBA (2019a) and NHI (2015b) provide further guidance on these considerations.

Skewed and curved I-girder bridges exhibit torsional displacements, or twisting, of the individual girders and of the overall bridge cross-section under load, including the loads during construction. As a result, the girder webs can only be plumb in one load condition. The fit condition of an I-girder bridge refers to the targeted girder dead load geometry for which the cross-frames or diaphragms are detailed to connect to the girders. The girder geometry used by the Fabricator/Detailer to detail the cross-frames or diaphragms is based on the vertical deflections provided in the contract documents that are associated with the selected fit condition.

The fit condition influences the vertical orientation of the girders under various stages of dead and live load, the associated rotation demands on the bearings, the forces required for assembly of the steel during construction, and the internal forces for which the cross-frames or diaphragms and girders must be designed (NSBA; 2016a; 2016b). The fit condition must always be indicated for the bridge types specified in Article 6.7.2 so that the Fabricator/Detailer can complete the shop drawings and fabricate the bridge components. Since the fit condition directly influences the cross-frame fabricated geometry, as well as the above items, the fit condition should ideally be selected by the Engineer, who best knows the loads and capacities of the structural members, in consultation with a Fabricator and Erector. The fit condition generally should be selected to accomplish the following objectives, in order of priority: 1) facilitate the construction of the bridge; 2) offset large girder dead load twist rotations and corresponding lateral movements at the deck joints and barrier rails, which

where:

L = actual span length bearing to bearing along the centerline of the bridge (ft)

R = girder radius at the centerline of the bridge (ft)

A Total Dead Load Fit should not be specified for curved I-girder bridges with or without skew and with a maximum L/R greater than 0.03. Such bridges may be detailed for Steel Dead Load Fit or No-Load Fit, unless the maximum L/R is greater than or equal to 0.2. In this case, either the bridge should be detailed for No-Load Fit or the additive locked-in force effects associated with the Steel Dead Load Fit detailing should be considered.

The provisions of Article 2.5.2.6.1 related to bearing rotations also shall be considered.

occur predominantly at sharply skewed abutment lines; 3) reduce the dead load forces in the cross-frames or diaphragms and the flange lateral bending stresses in the girders in straight skewed bridges; and 4) select the load condition in which the girders will be approximately plumb. The plumbness condition should not be specified by the Engineer; girder plumbness is dictated by the fit condition.

The three most common fit conditions are:

- No-Load Fit (NLF),
- Steel Dead Load Fit (SDLF), and
- Total Dead Load Fit (TDLF).

For the bridge types specified in Article 6.7.2, the contract documents should indicate the fit condition for which the cross-frames or diaphragms are to be detailed.

NLF refers to the condition where the cross-frames or diaphragms are detailed to fit to the girders in their fabricated, plumb, fully cambered position under zero load. In this case, the girder webs will be out-of-plumb after any dead load is applied, except at nonskewed bearing lines. At skewed bearing lines, this out-of-plumbness should be considered in the detailing of the deck, deck joint, barrier joint, and bearings, as applicable. Girder dead load layovers at highly skewed abutments can be substantial when NLF detailing is employed.

SDLF refers to the condition where the cross-frames or diaphragms are detailed to fit to the girders in their ideally plumb as-deflected positions under the self-weight of the steel at the completion of the erection. SDLF is common and effective for straight I-girder bridges and for most horizontally curved I-girder bridges (NSBA; 2016a, 2016b). SDLF is favored for ease of construction of straight skewed I-girder bridges since the steel dead load corresponds to the condition where all the girders are erected and all the cross-frames or diaphragms are connected. Straight bridges detailed for this condition typically require less forced fit-up of the cross-frames or diaphragms, particularly if the girders are allowed to deflect under their self-weight before installing the cross-frames or diaphragms. Where an SDLF is employed, dead loads applied after the completion of the steel erection will introduce a final and permanent twist into the girders.

TDLF refers to the condition where the cross-frames or diaphragms are detailed to fit to the girders in their ideally plumb as-deflected positions under the total dead load. The total dead load typically includes the weight of the concrete deck, but not the weight of any superimposed dead loads. In phased construction or where superimposed dead loads cause significant girder deflection, it may also be desirable to consider the effect of the superimposed dead loads. In the case of TDLF detailing, the Erector will leave the site with the girders out-of-plumb since the total dead load will not yet have been applied. However, TDLF gives approximately plumb girder webs once the bridge is subjected to its total dead load. For straight skewed I-girder bridges, or for

horizontally curved skewed I-girder bridges with L/R in all spans less than or equal to 0.03, TDLF can be effective for span lengths up to approximately 200 ft (NSBA; 2016a, 2016b). Practice has demonstrated that the use of TDLF for longer-span straight skewed bridges, and for horizontally curved bridges with or without skew and with a maximum L/R greater than 0.03, can potentially render the bridge unconstructable because the girders cannot be twisted as readily in these bridges to facilitate erection (NSBA; 2016a, 2016b). Curved I-girders, in particular, resist the twisting required to fit the steel together via their coupled resistance to major-axis bending and twisting. This behavior tends to increase the difficulty of fitting the steel together during the steel erection.

When either SDLF or TDLF is specified, the girders are fabricated plumb and are twisted out-of-plumb during steel erection in the opposite direction that they tend to twist under the application of the corresponding targeted dead load to connect them with the cross-frames or diaphragms. This compensating twist in the girders is achieved by introducing locked-in internal forces in the system during the erection.

Although the use of refined analysis methods is not required for these bridges, these methods, when utilized, do allow for consideration of dead load cross-frame or diaphragm forces and flange lateral bending stresses. In straight skewed I-girder bridges, these dead load force effects are partially offset by the corresponding locked-in force effects at the completion of the steel erection (White et al., 2012) (White et al., 2015). It is important to recognize that the dead load force effects, when determined from a refined analysis model, typically do not include the locked-in force effects due to SDLF or TDLF detailing of the cross-frames or diaphragms. That is, the analysis model corresponds to the assumption of NLF.

White et al. (2015) describe a procedure for directly determining the locked-in force effects from SDLF or TDLF detailing as part of a refined analysis. Otherwise, in lieu of considering the locked-in force effects directly within the structural analysis, the approximations discussed below may be employed. For straight skewed I-girder bridges detailed for TDLF where the skew index, I_s , defined in Article 4.6.3.3.2 is greater than 1.0, the recommendations provided in Article C6.7.4.2.1 to lessen transverse stiffness effects should be applied and the direct calculation of the influence of the dead-load fit detailing on the girder vertical reactions and girder major-axis bending stresses via a refined analysis should be considered. In addition, for curved and skewed I-girder bridges with a maximum L/R greater than 0.03, calculation of the influence of dead load fit detailing on the girder vertical reactions via a refined analysis should be considered (White et al., 2015). The following procedures do not address the effects due to the bracket loads supporting the eccentric deck overhangs during deck construction. These effects may be estimated

separately as described in Article C6.10.3.4.1 and combined as appropriate with the other dead load effects discussed below.

For straight skewed I-girder bridges that are detailed for TDLF, the total dead load cross-frame or diaphragm forces and flange lateral bending stresses, when determined from a refined analysis not including the influence of dead load fit detailing, may be reduced to account for the corresponding locked-in force effects introduced into the structural system during the steel erection. In this case, a net reduced load factor, $(\gamma_p)_{red}$, to be applied to the unfactored total dead load cross-frame or diaphragm forces and flange lateral bending stresses may be conservatively taken as:

$$(\gamma_p)_{red} = (\gamma_p - 0.4) \quad (C6.7.2-1)$$

where:

γ_p = the maximum load factor for *DC*, specified in Table 3.4.1-2, or the maximum load factor specified in Article 3.4.2.1 for *DC* and any construction loads that are applied to the fully erected steelwork, as applicable.

The above net reduced load factor, applied to the unfactored total dead load cross-frame or diaphragm forces and flange lateral bending stresses, gives a lower-bound estimate of the corresponding beneficial locked-in force effects from TDLF detailing (White et al., 2015). Smaller net reduced load factors may be applied to the unfactored cross-frame or diaphragm forces and flange lateral bending stresses at the discretion of the Owner. In straight skewed bridges detailed for TDLF, the Engineer should also check the cross-frame or diaphragm forces and the flange lateral bending stresses for the fit-up force effects during the steel erection. These effects may be estimated as the negative of the corresponding unfactored concrete dead load force effects, which should then be multiplied by γ_p (White et al., 2015).

White et al. (2015) recommend that the specified load factor, γ_p , should be applied directly to the *DC* cross-frame or diaphragm forces and flange lateral bending stresses for straight skewed bridges detailed for SDLF. Significant cross-frame or diaphragm force and flange lateral bending stress reductions are achievable in straight skewed bridges detailed for SDLF; however, in the most extreme cases studied by White et al. (2015), incidental and elastic deformation effects in the structural system lead to negligible corresponding locked-in force effects for SLDF. It should be emphasized that the best estimate of the internal force reductions, when either SDLF or TDLF is employed, is by calculation of the locked-in force effects directly within the structural analysis.

In curved I-girder bridges, the locked-in force effects tend to be additive with the corresponding dead load effects. These additive locked-in force effects tend to be

particularly significant for bridges with a maximum L/R greater than or equal to 0.2 that are detailed for SDLF (White et al., 2015). Detailing curved I-girder bridges with or without skew and with a maximum L/R greater than or equal to 0.2 for NLF avoids the introduction of these additional locked-in force effects. Should it be desired to detail such bridges for SDLF, NSBA (2016a) provides an approximate approach for estimating the additional locked-in force effects when these effects are not determined as part of a refined analysis. For bridges with smaller L/R that are detailed for an SDLF, the horizontal curvature effects are smaller, and hence the additive locked-in force effects are smaller and may be neglected.

The additional locked-in force effects are more significant for TDLF detailing; however, TDLF detailing is strongly discouraged for horizontally curved bridges with or without skew and with a maximum L/R greater than 0.03 (NSBA; 2016a, 2016b). Since the locked-in force effects from SDLF and TDLF detailing associated with horizontal curvature tend to be additive with the corresponding dead load force effects, the optional reduction of the total dead load cross-frame or diaphragm forces and flange lateral bending stresses discussed previously is not applicable to horizontally curved or curved and skewed bridges.

Various factors can cause the girders to deviate from the ideal plumb geometry under the targeted dead load condition, particularly when TDLF detailing is specified. These factors include connection tolerances, fabrication tolerances, accuracy of the structural analysis models, accuracy of the dead load deflection estimates, stiffness of the deck forming (which is typically neglected in analysis calculations), and sequential casting and early stiffness gains of the deck concrete. Except in unusual cases involving substantial global displacement amplification of a slender I-girder bridge unit in its noncomposite condition during the deck placement due to stability effects, such as discussed in Article 6.10.3.4.2, deviation from the ideal plumb condition due to the deflection of the structure generally has a negligible influence on the structural resistance (White et al., 2012). However, substantial deviation from the targeted geometry is an indication that the dead load internal forces and internal stresses in the structure may differ significantly from their calculated values. AASHTO/NSBA (2019b) suggests a tolerance on the deviation from the theoretical erected web position.

Shop assembly of the entire bridge or any significant portion of the bridge is not customary and is typically not needed, except possibly for highly complex framing detailed for NLF. Such a requirement adds unnecessary cost to projects that utilize less complex and more conventional framing. Full shop assembly cannot be done if the bridge has been detailed for TDLF.

Tub girders with properly designed top-flange lateral bracing effectively behave as closed sections, and as such, they are torsionally stiff. Straight or slightly curved

tub girders with top-flange lateral bracing, but without external intermediate cross-frames or diaphragms, generally exhibit little twist under noncomposite loading. Tub girders with longer spans and more significant curvature are potentially subject to more significant twisting, but this is often controlled and minimized by providing external intermediate cross-frames or diaphragms. Tub girders are typically designed and detailed to be oriented normal to the cross-slope of the roadway and their webs are detailed to be of equal depth (AASHTO/NSBA, 2007). Thus, the concepts of NLF, SDLF, and TDLF do not directly apply. Also, since tub girders are inherently torsionally stiff, it is difficult to twist them in the field to achieve fit-up of external cross-frames or diaphragms. As a result, tub girder external cross-frames or diaphragms are typically detailed and fabricated to fit under no-load or a specific intermediate steel dead load condition depending on the intended erection sequence. In addition, depending on the magnitude of their twist deformations, tub girders may need to be detailed and fabricated with a built-in reverse twist so that when they twist under dead load, they deflect to a position normal to the roadway cross-slope. The camber of the two webs in skewed and/or curved tub-girder bridges can be significantly different.

6.7.3—Minimum Thickness of Steel

Structural steel, including bracing, cross-frames, and all types of gusset plates, except for gusset plates used in trusses, webs of rolled shapes, closed ribs in orthotropic decks, fillers, and in railings, shall not be less than 0.3125 in. in thickness. The thickness of gusset plates used in trusses shall not be less than 0.375 in. The web thickness of rolled beams or channels shall not be less than 0.23 in.

For orthotropic decks, the deck plate thickness shall not be less than 0.625 in. or 4 percent of the larger spacing of the ribs, and the thickness of closed ribs shall not be less than 0.1875 in.

Where the metal is expected to be exposed to severe corrosive influences, it shall be specially protected against corrosion or sacrificial metal thickness shall be specified.

6.7.4—Diaphragms and Cross-Frames

6.7.4.1—General

Diaphragms or cross-frames may be placed at the end of the structure, across interior supports, and intermittently along the span. The design of diaphragms or cross-frames shall be investigated for all stages of assumed construction procedures and the final condition.

This investigation should include, but not be limited to, the following:

C6.7.3

For orthotropic decks, research and development and general design improvements domestically and abroad have demonstrated that a minimum deck plate thickness of 0.625 in. has addressed the causes of many problems resulting from overly flexible decks. Although analysis may indicate that deck plates less than 0.625 in. thick could be satisfactory, experience shows that a minimum thickness of 0.625 in. is advisable both from construction and long-term performance points of view.

C6.7.4.1

The arbitrary requirement for diaphragms or cross-frames spaced at not more than 25.0 ft in the AASHTO *Standard Specifications for Highway Bridges* (2002) has been replaced by a requirement for rational analysis to establish the necessary spacing according to the requirements specified herein.

- transfer of lateral wind loads from the bottom of the girder to the deck and from the deck to the bearings;
- provision of lateral support to the fascia girders between cross-frame or diaphragm locations to control torsional stresses and rotations due to loads applied to the overhangs, particularly during concrete deck placement;
- provision of stability bracing by controlling twist of the noncomposite girder during critical stages of construction;
- provision of stability bracing in regions of the girder where the bottom flange is subject to compression at the strength limit state by controlling lateral movement of the bottom flange or twist of the girder;
- consideration of any flange lateral bending effects; and
- distribution of vertical dead and live loads applied to the structure.

Metal stay-in-place deck forms shall not be assumed to provide adequate stability to the top flange in compression prior to curing of the deck.

If permanent cross-frames or diaphragms are included in the structural model used to determine force effects, they shall be designed for all applicable limit states for the calculated force effects. At a minimum, diaphragms and cross-frames shall be designed to transfer wind loads according to the provisions of Article 4.6.2.7 and shall meet all applicable slenderness requirements in Article 6.8.4 or Article 6.9.3. Force effects in diaphragm and cross-frame members in horizontally curved bridges, exceeding one or more of the conditions specified in Article 4.6.1.2.4 for neglecting the effects of curvature, shall be computed and considered in the design of the members and their connections for all applicable limit states.

Bracing of horizontally curved members is more critical than for straight members. Diaphragm and cross-frame members resist forces that are critical to the proper functioning of curved-girder bridges with larger degrees of curvature. Therefore, force effects in the bracing members must be computed and considered in the design of these members and their connections when one or more of the conditions specified in Article 4.6.1.2.4 for neglecting the effects of curvature in the analysis is exceeded.

Force demands in intermediate diaphragms or cross-frames, particularly those related to live loads on the completed structure, are generally small in straight I-girder bridges with normal supports or limited skews, as discussed below. As such, developing a refined analysis model to obtain diaphragm or cross-frame design forces for these simple bridge geometries is not typically warranted.

In contrast, intermediate diaphragms or cross-frames in straight I-girder bridges with more significant skew and curved I-girder bridges with or without skew are subjected to more substantial force effects, as discussed in Article C6.7.4.2.1. Force effects in diaphragms or cross-frames in horizontally curved I-girder systems with or without skew exceeding one or more of the conditions specified in Article 4.6.1.2.4b for neglecting the effects of curvature are typically computed using refined analysis methods because they transmit the forces necessary to provide equilibrium and as such, are considered primary members. Force effects in these members in straight I-girder bridges with more significant skew are also often computed using refined analysis methods, even though these members are classified as secondary members in these systems.

Reichenbach et al. (2021) investigate live-load force effects in a variety of I-girder bridge geometries, and observe that bridges exceeding the following skew, I_s , and connectivity, I_c , index limits typically produce significant load-induced cross-frame force effects, and therefore, evaluation of these members in I-girder bridges for all applicable limit states using refined analysis methods in accordance with Article 4.6.3 is warranted: curved bridges for which $I_c > 1$, skewed bridges for which $I_s > 0.3$, or curved and skewed bridges for which $I_c > 0.75$ and $I_s > 0.15$. I_s and I_c are defined in Article 4.6.3.3.2. These geometric limits were based on an evaluation of diaphragms and cross-frames specifically for the fatigue limit state under an assumed $(ADTT)_{SL}$ of 1,500 trucks per day and a 75-year fatigue design life. For values of $(ADTT)_{SL}$ exceeding 1,500 trucks per day or a fatigue design life exceeding 75 years, engineering judgment should be used when determining the applicability of the recommended limits provided herein. Similarly, engineering judgment should be used when evaluating the need for refined analysis to evaluate these members at the strength limit state.

As noted in Article C4.6.3.3.2, 3D analysis methods generally produce more accurate predictions of diaphragm and cross-frame force effects than 2D grid or plate and eccentric beam methods. For bridges that do not exceed the limits outlined above, the minimum design requirements specified herein and in Article 6.7.4.2.1 should be applied at a minimum.

If the diaphragm flanges or cross-frame chords are not attached directly to the girder flanges, forces from these elements are transferred through the connection plates. The eccentricity between the diaphragm flanges or cross-frame chords and the girder flanges should be recognized in the design of the connection plates and their connection to the web and flange.

The term connection plate as used herein refers to a transverse stiffener attached to the girder to which a cross-frame or diaphragm is connected.

Connection plates for diaphragms and cross-frames shall satisfy the requirements specified in Article 6.6.1.3.1. Where the diaphragm flanges or cross-frame chords are not attached directly to the girder flanges, provisions shall be made to transfer the calculated horizontal force in diaphragms or cross-frames to the flanges through connection plates, except in cases where less than full-depth end angles or connection plates are used for connecting intermediate diaphragms as permitted in Article 6.6.1.3.1.

At the end of the bridge and intermediate points where the continuity of the slab is broken, the edges of the slab shall be supported by diaphragms or other suitable means as specified in Article 9.4.4.

6.7.4.2—I-Section Members

6.7.4.2.1—General

Diaphragms or cross-frames for rolled beams and plate girders should be as deep as practicable, but at a minimum should be at least 0.5 of the beam depth for

C6.7.4.2.1

For the purpose of this Article, as it applies to horizontally curved girders, the term “normal” shall be taken to mean normal to a local tangent.

intermediate cross-frame or diaphragm from the support along the girder under consideration (White et al., 2015). The offsets should be maximized at the obtuse corners of the spans to the extent practicable. These practices help to alleviate the introduction of a stiff load path that will attract and transfer large transverse forces to the skewed support, particularly at the obtuse corners of a skewed span. In some cases, the limit of $0.4L_b$ may be difficult to achieve, in which case the offset should be made as large as practicable but not less than $4b_f$. At the acute corners of severely skewed bridge spans, the above requirements may result in an excessive unbraced length on the fascia girder. In this case, a cross-frame with top and bottom chords but without diagonal members can be framed from the first interior girder to the fascia girder at a small offset from the support, perpendicular to the girders, to avoid inducing a large transverse stiffness while also providing adequate lateral support to the fascia girder.

Where practicable, the smallest unbraced lengths between intermediate diaphragm or cross-frame locations within the bridge spans should not be less than $4b_f$ or $0.4L_b$, where b_f is defined in the above paragraph and L_b is the smallest unbraced length adjacent to the unbraced length under consideration. The use of unbraced lengths smaller than $4b_f$ or $0.4L_b$ tends to result in the associated cross-frames working more like a contiguous cross-frame line rather than a discontinuous one. Similar to the selection of the offsets from the skewed supports, the limit of $0.4L_b$ may be difficult to achieve in certain cases. In these situations, the value $4b_f$ is the recommended lower limit for the smallest unbraced lengths, offsets, or stagger distances.

White et al. (2015) recommend framing of the diaphragms or cross-frames within straight skewed spans using arrangements such as that shown in Figure C6.7.4.2.1-1 to both reduce the number of diaphragms or cross-frames required within the bridge as well as to reduce the overall transverse stiffness effects. In Figure C6.7.4.2.1-1, the diaphragms or cross-frames adjacent to the bearing lines are all placed at the same offset distance relative to the skewed bearing lines, satisfying the above offset recommendations. The other intermediate diaphragms or cross-frames are placed at a constant spacing along the span length to satisfy the flange resistance requirements given in these specifications. In addition, every other diaphragm or cross-frame is intentionally omitted within the bays between the interior girders of the bridge plan. This relaxes the large transverse stiffness that would otherwise be developed in the short diagonal direction between the obtuse corners of the span. This concept and other beneficial framing concepts are discussed further in NSBA (2016a).

Figure C6.7.4.2.1-1—Beneficial Staggered Diaphragm or Cross-frame Framing Arrangement for a Straight Bridge with Parallel Skew

At skewed interior piers in continuous-span bridges, NHI (2011) and White et al. (2015) find that transverse stiffness effects are alleviated most effectively by placing diaphragms or cross-frames along the skewed bearing line and locating normal intermediate diaphragms or cross-frames at greater than or equal to the minimum offset from the bearing lines discussed above. Framing of a normal intermediate cross-frame into or near a bearing location along a skewed support line is strongly discouraged unless the cross-frame diagonals are omitted (Helwig and Wang, 2003) (NSBA, 2016a).

For curved and skewed spans, diaphragms or cross-frames in the vicinity of skewed intermediate or end supports tend to generate the largest force effects. Bottom strut and diagonal members in cross-frame systems typically experience significantly more load than top strut members in composite systems (Reichenbach et al., 2021). Omitting diaphragms or cross-frames in the vicinity of skewed bearing lines can help to alleviate uplift at critical bearing locations; however, this is typically at the expense of larger diaphragm or cross-frame forces and larger bridge deflections compared to the use of contiguous intermediate diaphragm or cross-frame lines with the recommended offset provided at the skewed bearing lines. Contiguous diaphragm or cross-frame lines are necessary within the span of curved I-girder bridges to develop the width of the bridge structural system for resistance of the overall torsional effects. As such, the use of discontinuous diaphragm or cross-frame lines near a skewed bearing line in these bridge types involves competing considerations. Diaphragms or cross-frames can be omitted to alleviate uplift considerations at certain bearings, and potentially to relieve excessive diaphragm or cross-frame forces due to transverse stiffness effects in certain cases—for instance, if the horizontal curvature is relatively small and the skew is significant. However, omission of too many diaphragms or cross-frames may result in a larger than desired increase in the diaphragm or cross-frame forces and bridge system deflections due to the horizontal curvature effects when the bridge is significantly curved.

Larger diaphragm or cross-frame members can be used to satisfy higher force demands. However, an increased diaphragm or cross-frame stiffness often leads to larger forces in the members that are induced from differential girder displacements at either end of the brace due to geometric issues or live loads in systems with significant support skew or highly indeterminate systems. Thus, using exceedingly larger members is not always practical or economical.

For skewed diaphragms or cross-frames, connection plates should be oriented in the plane of the transverse bracing. The connection plate must be able to transfer force between the girder and the bracing without undue distortion. Welding of skewed connection plates to the girder may be problematic where the plate forms an acute angle with the girder.

The spacing of intermediate diaphragms and cross-frames in horizontally curved I-girder bridges in the erected condition is limited to $R/10$, which is consistent with past practice. The spacing is also limited to L_r from Eq. 6.10.8.2.3a-5, where L_r is a limiting unbraced length to achieve the onset of nominal yielding in either flange under uniform bending with consideration of compression flange residual stress effects prior to lateral-torsional buckling (LTB) of the compression flange. Limiting the unbraced length to L_r theoretically precludes elastic LTB of the compression flange. At unbraced lengths beyond L_r , significant flange lateral bending is likely to occur and the amplification factor for flange lateral bending specified in Article 6.10.1.6 will tend to become large even when an effective length factor for LTB and/or a moment-gradient factor, C_b , is considered.

Eq. C6.7.4.2.1-1 may be used as a guide for preliminary framing in horizontally curved I-girder bridges:

$$L_b = \sqrt{\frac{5}{3} r_\sigma R b_f} \quad (\text{C6.7.4.2.1-1})$$

where:

- b_f = flange width (ft)
- L_b = diaphragm or cross-frame spacing (ft)
- r_σ = desired bending stress ratio equal to $|f_r / f_{bu}|$
- R = girder radius (ft)

A maximum value of 0.3 may be used for the bending stress ratio, r_σ . Eq. C6.7.4.2.1-1 was derived from the V-load concept (Richardson, Gordon and Associates, 1976) and has been shown to yield a good correlation with three-dimensional finite-element analysis results if the cross-frame spacing is relatively uniform (Davidson et al., 1996).

The spacing, L_b , of intermediate diaphragms or cross-frames in horizontally curved I-girder bridges shall not exceed the following in the erected condition:

$$L_b \leq L_r \leq R/10 \quad (\text{6.7.4.2.1-1})$$

where:

- L_r = limiting unbraced length determined from Eq. 6.10.8.2.3a-5 (ft)
- R = minimum girder radius within the panel (ft)

In no case shall L_b exceed 30.0 ft.

6.7.4.2.2—Stability Bracing Requirements

In addition to the minimum design requirements specified in Article 6.7.4.1, diaphragms or cross-frames for all rolled-beam and plate-girder bridges shall satisfy the following stability bracing stiffness requirement for the applicable noncomposite *DC* loads and any construction loads applied to the fully erected steelwork:

$$(\beta_T)_{act} \geq (\beta_T)_{req} \quad (\text{6.7.4.2.2-1})$$

in which:

C6.7.4.2.2

The provisions in this article are adapted from the 2010 AISC *Specification*, Appendix 6.3.2a, as modified based on Liu et al. (2020) and Liu and Helwig (2020). These provisions may be applied to skewed I-girder bridges with discontinuous cross-frames or diaphragms but should not be applied to straight skewed I-girder bridges utilizing lean-on bracing systems. Such systems should be instead investigated as described in Helwig and Wang (2003).

Effective stability bracing can be achieved by either preventing lateral movement of the compression flange

$(\beta_T)_{req}$ = required stiffness of the torsional brace system (kip-in./rad) calculated as follows:

- For diaphragms and cross-frames whose depth is at least 0.8 times the beam or girder depth, attached to full-depth connection plates positively attached to both flanges:

$$= \frac{2.4L}{\phi_{sb} nEI_{yeff}} \left(\frac{M_u}{C_b} \right)^2 \quad (6.7.4.2.2-2)$$

- Otherwise:

$$= \frac{3.6L}{\phi_{sb} nEI_{yeff}} \left(\frac{M_u}{C_b} \right)^2 \quad (6.7.4.2.2-3)$$

I_{yeff} = effective out-of-plane moment of inertia of the girder (in.⁴) calculated as follows:

- For doubly symmetric girders:

$$= I_y \quad (6.7.4.2.2-4)$$

- For singly symmetric girders:

$$= I_{yc} + \left(\frac{t}{c} \right) I_{yt} \quad (6.7.4.2.2-5)$$

where:

- ϕ_{sb} = resistance factor for stability bracing specified in Article 6.5.4.2
- c = distance from the centroid of the girder section at the brace point under consideration to the centroid of the compression flange (in.). The distance shall be taken as positive.
- C_b = moment-gradient modifier within the critical unbraced beam or girder segment under consideration determined as specified in Article 6.10.8.2.3b, 6.10.8.2.3c, A6.3.3.2, or A6.3.3.3, as applicable
- I_y = noncomposite moment of inertia about the vertical centroidal axis of the girder section at the brace point under consideration (in.⁴)
- I_{yc}, I_{yt} = moments of inertia of the girder compression and tension flange, respectively, about the vertical centroidal axis of the section at the brace point under consideration (in.⁴)
- L = length of the span under consideration (in.) For a cross-frame or diaphragm located at an interior support, the average length of the spans on either side of the interior support shall be used for L .

with lateral bracing (Yura, 2001) or by controlling twist of the cross-section with torsional bracing. Cross-frames and diaphragms enhance the LTB resistance of longitudinal beams and girders by restraining twist of the cross-section at discrete locations along the length and are therefore categorized as torsional bracing. Although the beam or girder bending moments during construction are smaller in magnitude than the bending moments acting on the completed structure, the critical stage for stability bracing is during construction, including when the fully erected steelwork supports the applicable *DC* loads and any construction loads acting on the noncomposite structure during the deck casting. Cross-frames and diaphragms typically serve as the only source of bracing to the beams or girders at this stage, although in some situations, lateral bracing may also be necessary to help control lateral deflections of the fully erected steelwork due to wind and/or to provide additional stability to the fully erected steelwork during construction, as discussed further in Articles 6.7.5.2 and 6.10.3.4.2.

In the completed structure, the shear studs and composite deck provide continuous lateral and torsional restraint to the top compression flange in regions of positive flexure. Even in the negative moment regions, where shear studs may be omitted, the deck provides continuous lateral restraint to the top flange as well as some tipping restraint to limit flange twist. In this case, the demand on cross-frames and diaphragms is substantially reduced from the case where the deck is either not present or its stiffness is not yet fully effective; that is, when the stiffness of the deck is fully effective, the cross-frame diagonals mainly serve as struts that laterally restrain the bottom compression flange. The cross-frame brace stiffness in this case greatly exceeds the stiffness as a pure torsional brace. The bridge bearings and anchor bolts provide some additional lateral and torsional restraint to the bottom compression flange in these regions as well. Therefore, the stability bracing requirements for cross-frames or diaphragms are not considered to be critical for the design of the composite structure at the strength limit state. These requirements should instead be checked for the critical construction stage, which generally occurs during the placement of the concrete deck.

The stiffness requirement for the torsional brace system specified in Eqs. 6.7.4.2.2-2 and 6.7.4.2.2-3 is based on the buckling strength equation for a beam with a continuous torsional brace along its length, derived by Taylor and Ojalvo (1966), and modified for cross-section distortion by Yura (2001). Stability bracing provisions are generally a function of the ideal brace stiffness, which is the stiffness required for a perfectly straight member to reach a load level corresponding to buckling between brace points. To account for the impact of imperfections, a stiffness larger than the ideal value is provided to control deformations and brace forces. Past studies on column and frame bracing have shown that providing twice the ideal stiffness limits the amount of deformation

- M_u = factored major-axis bending moment for the limit-state load combination specified in Article 3.4.1 or 3.4.2.1, as applicable (kip-in.). In regions of positive flexure, use the maximum factored major-axis bending moment within the region. In regions of negative flexure, use the factored major-axis bending moment at the interior support under consideration.
- n = number of intermediate brace points within the span under consideration
- t = distance from the centroid of the girder section at the brace point under consideration to the centroid of the tension flange (in.). The distance shall be taken as positive.

to a value equal to the initial imperfection. The expression given in Eq. 6.7.4.2.2-2 is related to twice the ideal stiffness. Liu et al. (2020) studied torsional beam bracing and found that providing twice the ideal stiffness resulted in larger deformations for systems with the critical shape imperfection and therefore recommended a value corresponding to three times the ideal stiffness, which is represented by Eq. 6.7.4.2.2-3 with the constant 3.6. Han and Helwig (2020) demonstrated full-depth cross-frames generally result in significantly different imperfection shapes compared to the critical shape that is assumed in torsional stability bracing formulations. The resulting deformations and brace forces with the corresponding imperfection are not as large as the cases with the critical shape. Therefore, cross-frames with depths that are at least 0.8 times the beam or girder depth have stiffness requirements based upon twice the ideal stiffness given by Eq. 6.7.4.2.2-2. Cross-frames with depths less than 0.8 times the beam depth should be designed using three times the ideal stiffness as given in Eq. 6.7.4.2.2-3. Diaphragms in through-girder bridges and in rolled-beam bridges are typically less than 0.8 times the beam or girder depth and therefore Eq. 6.7.4.2.2-3 should be used to determine the required stiffness.

A cross-frame or diaphragm on only one side of the beam or girder should be considered a brace point. In lieu of a more refined approach, for spans with discontinuous or staggered cross-frame or diaphragm layouts, the number of brace points, n , in Eqs. 6.7.4.2.2-2, 6.7.4.2.2-3, 6.7.4.2.2-14, and 6.7.4.2.2-15 may be taken as the maximum of the total number of intermediate brace points on each side of the beam or girder within the span under consideration. As an example, for an interior girder with eight brace points on one side and seven brace points on the other, n is to be taken as 8. For a fascia girder with eight brace points on only one side, n is also to be taken as eight. The value of n is to be taken as the number of intermediate brace points within the span under consideration; that is, the number of brace points in-between the supports for that span. At end supports, the stability bracing requirements for the cross-frames or diaphragms may be taken the same as for the intermediate cross-frames within the span under consideration. For spans without intermediate cross-frames, the stability bracing requirements for the support cross-frames may be computed assuming n equal to 1.

The actual overall stiffness of a torsional bracing system is significantly impacted not only by the stiffness of the diaphragm or cross-frame brace itself, but also by the girder web cross-sectional distortion at the brace point and by the in-plane stiffness of the girders that it braces. The combined effects are commonly represented as springs in series in Eq. 6.7.4.2.2-6. The total system stiffness, $(\beta_T)_{act}$, is always less than minimum of the β_{br} , β_{sec} , and β_g terms.

The equations specified herein for estimating the brace stiffness in the plane of a diaphragm or cross-frame

In lieu of a more refined analysis, the actual overall stiffness of the torsional bracing system, $(\beta_T)_{act}$, shall be calculated as follows:

$$(\beta_T)_{act} = \frac{1}{\left(\frac{1}{\beta_{br}} + \frac{1}{\beta_{sec}} + \frac{1}{\beta_g} \right)} \quad (6.7.4.2.2-6)$$

in which:

β_{br} = brace stiffness of the diaphragm or cross-frame that restrains twist of a beam or girder (kip-in./rad.) determined as follows:

- For an X-type cross-frame, tension-only diagonal system, or a Z-type cross-frame with a single compression diagonal:

$$= \frac{ES^2 h_b^2}{\frac{2L_d^3}{A_d} + \frac{S^3}{A_s}} \quad (6.7.4.2.2-7)$$

- For an X-type cross-frame, compression-diagonal system:

$$= \frac{A_d ES^2 h_b^2}{L_d^3} \quad (6.7.4.2.2-8)$$

- For a K-type cross-frame:

$$= \frac{2ES^2 h_b^2}{\frac{8L_d^3}{A_d} + \frac{S^3}{A_s}} \quad (6.7.4.2.2-9)$$

- For a diaphragm attached at or above mid-height of the beam or girder:

$$= \frac{6EI_b}{S} \quad (6.7.4.2.2-10)$$

- For a diaphragm attached below mid-height of the beam or girder:

$$= \frac{2EI_b}{S} \quad (6.7.4.2.2-11)$$

that restrains twist of a beam or girder, β_{br} , are taken from Yura, (2001).

In computing the brace stiffness, β_{br} , in Eqs. 6.7.4.2.2-7 through 6.7.4.2.2-9, the softening effect of eccentric end connections on the stiffness of single-angle and tee-section cross-frame members is to be considered in accordance with the provisions of Article 4.6.3.3.4c; that is, the cross-sectional area of the cross-frame members is to be reduced by the factor specified herein to account for the inherent flexibility of the connections when investigating the noncomposite condition during construction.

The position of the torsional brace with respect to the beam or girder cross-section does not impact its effectiveness in terms of girder response. Torsional bracing attached at the level of the tension flange is just as effective as a brace attached at mid-depth or at the level of the compression flange as long as distortion of the cross-section is controlled. Although the beam or girder response is generally not sensitive to the brace location, the position of the brace on the cross-section influences the stiffness of the brace itself. For example, a torsional brace attached below mid-height of the beam or girder will tend to bend in single curvature, as reflected in Eq. 6.7.4.2.2-11, while a brace attached at or above mid-height of the beam or girder will tend to bend in reverse curvature, as reflected in Eq. 6.7.4.2.2-10.

For skewed intermediate cross-frames or diaphragms, the stiffness given by Eqs. 6.7.4.2.2-7 through 6.7.4.2.2-11 should be modified to account for the reduced effectiveness of a skewed cross-frame relative to the longitudinal axis of the girder and the additional member lengths in the skewed orientation. In such cases, $\beta_{br,skew} = \beta_{br} \cos^2 \theta$, where θ is the angle of a skewed intermediate diaphragm or cross-frame relative to a line normal to the longitudinal axis of the bridge (Wang and Helwig, 2008), as limited by the provisions of Article 6.7.4.2.1. For skewed intermediate and support cross-frames, L_d in Eqs. 6.7.4.2.2-7 through 6.7.4.2.2-9, as applicable, should be taken as the actual length of the diagonal member; that is, the length of the member along the skew, and S in Eqs. 6.7.4.2.2-7 through 6.7.4.2.2-11 for skewed intermediate and support cross-frames or diaphragms, as applicable, should be taken as the beam or girder spacing measured along the skew.

At skewed end or interior supports, cross-frames or diaphragms are routinely oriented about an axis parallel to the skewed support line, which can result in a skew angle that exceeds 20 degrees. In these instances, the effective brace stiffness can be significantly impacted by the skew angle, particularly when bent-plate connections are utilized. Despite this apparent stiffness reduction, there are several mitigating factors at these support regions, including the tipping restraint provided by bridge bearings, that improve the effectiveness of the brace and the LTB resistance of the girder. Therefore, the calculation of $\beta_{br,skew}$ does not need to be considered for skewed cross-frames or diaphragms at end or interior

β_{sec} = cross-sectional distortion stiffness for stability bracing (kip-in./rad.) determined as follows:

- For diaphragms and cross-frames, whose depth is at least 0.8 times the beam or girder depth, attached to full-depth connection plates positively attached to both flanges:
= ∞ (infinity)
- Otherwise:

$$\beta_{seci} = \frac{3.3E}{h_i} \left(\frac{D}{h_i} \right)^2 \left(\frac{1.5h_i t_w^3}{12} + \frac{t_s b_s^3}{12} \right) \quad (6.7.4.2.2-12)$$

β_g = effective in-plane girder stiffness for stability bracing (kip-in./rad.)

$$= \frac{24(n_g - 1)^2 S^2 EI_x}{n_g L^3} \quad (6.7.4.2.2-13)$$

where:

- A_d = gross cross-sectional area of a cross-frame diagonal member (in.²). For single-angle and tee-section members, the area shall be multiplied by 0.65.
- A_s = gross cross-sectional area of a cross-frame strut (in.²). For single-angle and tee-section members, the area shall be multiplied by 0.65.
- b_s = for a connection plate or end angle on only one side of the web, width of the connection plate or projecting leg size of the end angle (in.). For connection plates or end angles on both sides of the web, total combined width of the connection plates or projecting leg sizes of the end angles (in.)
- D = web depth (in.)
- h_b = height of the cross-frame measured between the centroids of the top and bottom struts, or depth of the diaphragm, as applicable (in.)
- h_i = for less than full-depth connection plates or end angles, distances along the web from

supports. As an alternative to bent-plate connections, the use of half-round bearing stiffeners is recommended to increase the connection stiffness, the torsional warping restraint, and the LTB resistance of the girder, as discussed further in Articles C6.10.8.2.3a and CA6.3.3.1.

Cross-sectional distortion significantly impacts the behavior of beams with relatively shallow braces with respect to the beam or girder depth. The portion of the web that impacts distortion is the region above and below the brace. Therefore, web distortion essentially cannot occur for cross-frames or diaphragms that are nearly the full depth of the web. For braces that are less than the full web depth, distortion is controlled with the connection plates. The impact of cross-sectional distortion stiffness is accounted for with the term, β_{sec} , in the calculation of the actual overall bracing system stiffness in Eq. 6.7.4.2.2-6. For cross-frames or diaphragms whose depth is at least 0.8 times the beam or girder depth, attached to full-depth connection plates positively attached to both flanges as specified in Article 6.6.1.3.1, the term, β_{sec} , is sufficiently large such that web distortion is generally not an issue (Yura, 2001). In such cases, β_{sec} is taken equal to infinity, and only the β_{br} and β_g terms need to be considered, as applicable. Otherwise, Eq. 6.7.4.2.2-12 is to be used to compute β_{seci} for the portions of the web above and below a less than full-depth connection plate or end angle, or above and below the cross-frame or diaphragm member, as applicable. In such cases,

$$1/\beta_{sec} = \sum (1/\beta_{seci})$$

Stability-induced forces result in end moments acting on cross-frames or diaphragms that are equilibrated by a vertical shear forces acting on the longitudinal girders. These vertical shear forces induce vertical deflections of the girders in addition to the deflections caused by the vertical load effects; these additional deflections represent a reduction in the effective stiffness of the girder, which leads to a decrease in the effectiveness of the cross-frames or diaphragms as stability bracing. The magnitude of the shear forces and resulting girder deflections is related to the number of girders, their in-plane flexural stiffness, and the overall bridge width in Eq. 6.7.4.2.2-13. Narrow I-girder bridge units are most impacted by the in-plane girder effects. For cases in which the β_g term dominates the overall system stiffness in Eq. 6.7.4.2.2-6, such as I-girder bridge units with three or fewer girders, then global displacement amplification should also be checked based on the provisions specified in Article 6.10.3.4.2.

		the top and bottom of the connection plate or end angle to the adjacent flange; otherwise, distances along the web from the top and bottom of the cross-frame or diaphragm member to the adjacent flange (in.)
I_b	=	moment of inertia of the diaphragm member about the horizontal centroidal axis of the section (in. ⁴)
I_x	=	noncomposite girder moment of inertia about the horizontal centroidal axis of the section at the brace point under consideration (in. ⁴)
L_d	=	length of a diagonal member (in.)
n_g	=	number of girders within the span under consideration connected by the diaphragms or cross-frames
S	=	beam or girder spacing (in.)
t_s	=	thickness of the connection plate or projecting leg of the end angle (in.)
t_w	=	web thickness (in.)

Should Eq. 6.7.4.2.2-1 not be satisfied, the following alternatives may be considered:

- The addition of flange-level lateral bracing or a hardened placement of the concrete deck over a distance of 20 to 25 percent of the span length adjacent to each support of the span under consideration may be considered. When this alternative is used, $(\beta_T)_{req}$ in Eq. 6.7.4.2.2-2 or 6.7.4.2.2-3, as applicable, shall be multiplied by 0.70;
- The effective out-of-plane moment of inertia of the girders may be increased and/or the diaphragm or cross-frame spacing may be decreased in the span under consideration until Eq. 6.7.4.2.2-1 is satisfied; or
- An elastic buckling analysis using a three-dimensional shell-element model that captures the significant aspects of the nonprismatic geometry may be conducted to investigate the global lateral-torsional buckling stability of the span under consideration for the applicable noncomposite DC loads and any construction loads applied to the fully erected steelwork.

In lieu of a more refined analysis, diaphragms or cross-frames in straight rolled-beam or plate-girder bridges with or without skew, and in horizontally curved

In longer-span bridges, if the girders and cross-frames within the span under consideration otherwise meet their pertinent design requirements, but do not satisfy the applicable stability bracing stiffness requirement given by Eq. 6.7.4.2.2-1, one recommended alternative is to add flange-level lateral bracing or a hardened placement of the concrete deck extending over a portion of the length of the span adjacent to each support. Yura et al. (2008) suggest that appropriately sized top-flange lateral bracing provided over a distance of 20 percent of the span length at both ends of the span develops the equivalent of a fixed-end condition for global lateral-torsional buckling; the same reference also includes equations that can be used to size the lateral bracing members. A range of 20 to 25 percent of the span length at both ends of the span is suggested herein to accommodate most typical cross-frame and diaphragm spacings. A similar range of the span is recommended for a hardened placement of the concrete deck at each end. The angle of the lateral bracing diagonal with respect to the horizontal should not be less than 30 degrees or greater than 60 degrees. For cross-sections with more than three girders, the lateral bracing should be placed in the outer bays only. When a partial-length top-flange lateral bracing system is provided, bottom-flange lateral bracing could also be provided to create a pseudo-closed box section and further increase the torsional stiffness of the girders. If bottom-flange lateral bracing is provided, the bracing system may be subject to significant live load forces and associated concerns with fatigue in the finished structure. Designs with top- and bottom-flange lateral bracing may also exhibit challenging constructability and fit-up issues.

Traditionally, Engineers have often designed diaphragms or cross-frames for bridges without significant skew or curvature based on wind loads and

rolled-beam or plate-girder bridges satisfying all the conditions specified in Article 4.6.1.2.4b for neglecting the effects of curvature, shall also satisfy the following stability bracing strength requirement for the applicable noncomposite *DC* loads and any construction loads applied to the fully erected steelwork calculated as follows:

- For diaphragms and cross-frames, whose depth is at least 0.8 times the beam or girder depth, attached to full-depth connection plates positively attached to both flanges:

$$M_{br} = \frac{2.4L}{nEI_{yeff}} \left(\frac{M_u}{C_b} \right)^2 \left(\frac{L_b}{500h_o} \right) \quad (6.7.4.2.2-14)$$

- Otherwise:

$$M_{br} = \frac{3.6L}{nEI_{yeff}} \left(\frac{M_u}{C_b} \right)^2 \left(\frac{L_b}{500h_o} \right) \quad (6.7.4.2.2-15)$$

where:

- h_o = distance between the flange centroids of the girder section at the brace point under consideration (in.)
- L = length of the span under consideration (in.). For a cross-frame or diaphragm located at an interior support, the average length of the spans on either side of the interior support shall be used for L .
- L_b = unbraced length of the segment under consideration (in.). Use the average unbraced length when investigating a point adjacent to two unbraced segments.
- M_{br} = required strength of a torsional brace (kip-in.)
- n = number of intermediate brace points within the span under consideration

individual member slenderness criteria, as calculated force effects in these members are typically not available from the analysis. In most cases, standard diaphragm or cross-frame designs, based on generic calculations and/or successful past use, and requiring no bridge-specific analysis by the Engineer, have been utilized. While such approaches have proven adequate, the requirements herein are intended to provide a method for Engineers to ensure that these members have adequate strength and stiffness, in the absence of any calculated force effects other than wind, to act as effective torsional braces for the longitudinal beam or girder for loads applied to the fully erected steelwork during construction. Alternatively, stability bracing forces can be determined directly by a large-displacement analysis provided the effects of imperfections are considered.

The bracing strength requirement specified in Eqs. 6.7.4.2.2-14 and 6.7.4.2.2-15 is equivalent to the product of the required stiffness of the torsional brace system given by Eq. 6.7.4.2.2-2 and Eq. 6.7.4.2.2-3, respectively, and an initial twist imperfection, which is assumed to be the critical shape imperfection that results in the largest brace forces. The resistance factor in Eq. 6.7.4.2.2-2 and Eq. 6.7.4.2.2-3 is not included since a resistance factor is included when calculating the factored resistance of the bracing member. The assumed critical shape imperfection for torsional bracing consists of a lateral sweep of the compression flange equal to $L_b/500$ and a straight tension flange, producing an initial twist equal to $L_b/500h_o$, where L_b is the unbraced length and h_o is the distance between flange centroids (Wang and Helwig, 2005). Although the depth to be used in computing the required strength of a torsional brace, M_{br} , from Eq. 6.7.4.2.2-14 or Eq. 6.7.4.2.2-15, as applicable, is theoretically equal to the distance, h_o , between the flange centroids of the girder section at the brace point under consideration, for simplicity, the web depth, D , may be conservatively substituted for h_o in Eq. 6.7.4.2.2-14 and Eq. 6.7.4.2.2-15, if desired. If the web depths of the adjacent girders are different at the two ends of the cross-frame or diaphragm under consideration, the average depth may be used.

To determine the critical unbraced segment within the span under consideration, Eq. 6.7.4.2.2-2 or 6.7.4.2.2-3 and Eq. 6.7.4.2.2-14 or 6.7.4.2.2-15, as applicable, should be evaluated for the unbraced segment containing the point of maximum positive moment, or the segments adjacent to that point if a brace is located right at that point, and for the unbraced segments immediately adjacent to the interior piers. Regions of positive flexure have smaller moment magnitudes but typically have C_b values close to unity, especially for cases with many intermediate braces between the supports; for simplicity, C_b may be taken equal to 1.0 for the evaluation of the segment or segments adjacent to the point of maximum positive moment. Regions of negative flexure adjacent to interior piers, although generally having larger moment magnitudes, are aided by steeper moment gradients, i.e., larger C_b factors,

and restraint offered by the supports. An appropriate value of C_b should be calculated for the evaluation of the segments adjacent to interior piers. Regions subject to reverse curvature bending do not significantly alter the torsional brace requirements (Helwig and Yura, 2022). For a given span, the critical unbraced segment for each respective stability requirement is the segment that maximizes that requirement. The resulting maximum requirements, as applicable, should then be applied to all the cross-frames or diaphragms within that span.

For skewed intermediate cross-frames or diaphragms, the required strength of a torsional brace given by Eq. 6.7.4.2.2-14 or Eq. 6.7.4.2.2-15, as applicable, should be modified to account for the additional brace forces developed in the skewed orientation. In such cases, $M_{br, skew} = M_{br} / \cos \theta$, where θ is the angle of a skewed intermediate diaphragm or cross-frame relative to a line normal to the longitudinal axis of the bridge (Wang and Helwig, 2008), as limited by the provisions of Article 6.7.4.2.1.

The required bracing strength, M_{br} , from Eq. 6.7.4.2.2-14 or Eq. 6.7.4.2.2-15, as applicable, is converted to stability bracing forces in cross-frame members by dividing M_{br} by the distance between the centroids of the top and bottom struts, h_b , to obtain the required stability strut forces, F_{br} . The required stability forces in the diagonals may be obtained by multiplying F_{br} by L_d/S for an X-type cross-frame compression-diagonal configuration, and by $2L_d/S$ for a K-type cross-frame configuration and for an X-type tension-only diagonal cross-frame configuration, where L_d is the length of the diagonal and S is the beam or girder spacing. This is demonstrated schematically in Figure C6.7.4.2.2-1. The required stability bracing forces are combined with the force effects produced from other concurrently acting load cases during construction, as determined from a first-order elastic analysis, in accordance with the applicable limit-state load combination specified in Articles 3.4.1 or 3.4.2.1.

Despite select top and bottom struts being represented as zero-force members in Figure C6.7.4.2.2-1, these members are essential to the effectiveness of the brace and the overall stability of the girder. Therefore, it is recommended to include both top and bottom strut members in X- and K-type cross-frames (AASHTO/NSBA, 2020).

X-Frame: Tension-Only Diagonal System**X-Frame: Compression Diagonal System****K-Frame**

Figure C6.7.4.2.2-1—Distribution of the Required Bracing Moment, M_{br} , to Cross-Frame Members in Various Configurations

The stability bracing forces determined from Eq. 6.7.4.2.2-14 or Eq. 6.7.4.2.2-15 as applicable, or alternatively from a large-displacement analysis considering nonlinear geometry, are to be considered an independent load effect. Given that the stability bracing forces are based on the factored beam or girder moment, M_r , an additional load factor is not to be applied to these forces.

6.7.4.3—Composite Box-Section Members

Diaphragms shall be provided within composite box-section members at each support to resist cross-section distortion of the box, and shall be designed to resist torsional moments in the box and transmit vertical and lateral forces from the box to the bearings.

For cross-sections consisting of two or more boxes, external cross-frames or diaphragms shall be used between the boxes at end supports. External cross-frames or diaphragms shall be provided between girder lines at interior supports, unless analysis indicates that the boxes are torsionally stable without these members, particularly during erection. Internal cross-frames or diaphragms

C6.7.4.3

External diaphragms with aspect ratios, or ratios of length to depth, less than 4.0 and internal diaphragms act as deep beams and should be evaluated by considering principal stresses rather than by simple beam theory. Fatigue details on these diaphragms and at the connection of the diaphragms to the flanges should be investigated considering the principal tensile stresses.

Boxes may undergo excessive rotation in some cases when the concrete deck is placed if intermediate diaphragms or cross-frames are not provided between boxes. If analysis shows that such rotations are anticipated, temporary cross-frames may be employed.

shall be provided at locations of external cross-frames or diaphragms.

Internal diaphragms provided for continuity or to resist torsional forces generated by structural members shall be connected to the webs and flanges of the box section. An access hole at least 18.0 in. wide and 24.0 in. high should be provided within each internal intermediate diaphragm. Design of the diaphragm shall consider the effect of the access hole on the stresses. Reinforcement around the hole may be required.

Intermediate internal diaphragms or cross-frames shall be provided. For all single box sections, horizontally curved sections, and multiple box sections in cross-sections of bridges not satisfying the requirements of Article 6.11.2.3 or with box flanges that are not fully effective according to the provisions of Article 6.11.1.1, the spacing of the internal diaphragms or cross-frames shall not exceed 40.0 ft.

Webs of internal and external diaphragms shall satisfy Eq. 6.10.1.10.2-1. The nominal shear resistance of internal and external diaphragm webs shall be determined from Eq. 6.10.9.3.3-1.

Removal of such temporary members may lead to failure of remaining bolts, creating a safety concern. The effect of the release of bracing forces on the bridge can be investigated by considering the effect of reversal of member loads. Removal of temporary cross-frames having large forces may cause increased deck stresses.

Until the deck on a tub section hardens, internal cross-frames or diaphragms and lateral top-flange bracing are required to stabilize the tub section. For straight boxes without skew satisfying the requirements of Article 6.11.2.3 and with fully effective box flanges, transverse bending stresses and longitudinal warping stresses due to cross-section distortion have often been shown to be small (Johnston and Mattock, 1967) and may be neglected. Torsion may be significant, however, if the deck weight acting on the box is unsymmetrical. For straight and horizontally curved tub girders with a full-length top lateral bracing system, Armijos-Moya et al. (2019) recommend that internal cross-frames or diaphragms be provided at every other panel point of the top lateral bracing system, with single-angle struts provided between the top flanges of the tub section at the remaining intermediate panel points, to reduce fabrication costs without hindering the structural stability or torsional response of the girder. Fewer internal cross-frames or diaphragms also make the tub girders easier for inspection personnel to walk through the boxes. When a partial-length top lateral bracing system is provided for straight tub girders or horizontally curved tub girders satisfying all the conditions specified in Article 4.6.1.2.4c for neglecting the effects of curvature, additional internal cross-frames or diaphragms should be placed at the transition points between the laterally braced and unbraced sections, and at midspan, to control distortion of the cross-section and retain the torsional stiffness of the girder. The transition point is the region between a lateral truss panel with a diagonal and a panel without a diagonal as indicated in Figure C6.7.4.3-1.

Figure C6.7.4.3-1—Transition Point Between the Laterally Braced and Unbraced Sections in a Partial-Length Top Lateral Bracing System

Internal cross-frames or diaphragms should also be placed near both sides of field splices in all cases. The Engineer should also consider the need for additional temporary or permanent internal cross-frames or diaphragms, which may be required for transportation, construction, and near the lifting points of each shipping piece. To simplify the detailing of the top lateral bracing connections, the lateral bracing diagonal working points

may be offset up to five percent of the panel point length from the strut working point, which will not significantly affect the global behavior of the girder (Armijos-Moya et al., 2019).

Cross-sectional distortion stresses are typically controlled by the internal cross-frames or diaphragms, with the spacing of these members not to exceed 40.0 ft for the cases specified herein. For the specific cases listed in Article 6.11.1.1, transverse bending stresses due to cross-section distortion are explicitly limited to 20.0 ksi at the strength limit state. Adequate internal cross-frames or diaphragms must be introduced to meet this limit and should also be designed to control the longitudinal warping stresses due to the critical factored torsional loads. Such stresses should not exceed approximately ten percent of the longitudinal stresses due to major-axis bending at the strength limit state. Transverse bending stresses and longitudinal warping stresses due to cross-section distortion can be determined using the beam-on-elastic-foundation or BEF analogy presented by Wright and Abdel-Samad (1968a). The recommended spacings described above should satisfy these limits in the majority of cases. Fan and Helwig (2002) provide an approach to estimate the axial loads in diagonals and struts of internal cross-frames due to cross-section distortion during the deck placement, which is when cross-sectional distortion effects are likely to be more significant.

Where distortion of the section is adequately controlled by the internal cross-frames or diaphragms, acting in conjunction with a top lateral bracing system in the case of tub sections, the St. Venant torsional inertia, J , for a box section may be determined as:

$$J = 4 \frac{A_o^2}{\sum \frac{b}{t}} \quad (\text{C6.7.4.3-1})$$

where:

- A_o = area enclosed by the box section (in.²)
- b = width of rectangular plate element (in.)
- t = thickness of plate (in.)

In tub sections with inclined webs with a slope exceeding 1 to 4 and/or where the unbraced length of the top flanges exceeds 30.0 ft, additional intermediate internal cross-frames, diaphragms, or struts may be required to increase the resistance of discretely braced top flanges of tub sections to lateral bending resulting from a uniformly distributed transverse load acting on the flanges. This lateral load results from the change in the horizontal component of the web dead load shear plus the change in the St. Venant torsional dead load shear per unit length along the member, and is discussed further in Article C6.11.3.2.

Because of the critical nature of internal and external diaphragms, particularly at supports, any reliance on post-buckling resistance is not advisable. Satisfaction of

Eq. 6.10.1.10.2-1 ensures that theoretical bend buckling of internal and external diaphragm webs will not occur for elastic stress levels at or below the yield stress.

Limiting the nominal shear resistance of diaphragm webs to the shear buckling or shear yield resistance according to Eq. 6.10.9.3.3-1 prevents any reliance on post-buckling shear resistance. Bearing stiffeners on internal diaphragms act as transverse stiffeners in computing the nominal shear resistance.

A portion of the box flange width equal to six times its thickness may be considered effective with an internal diaphragm.

The attachment of internal cross-frame connection plates to box flanges is discussed further in Article C6.6.1.3.1.

6.7.4.4—Noncomposite Box-Section Members

6.7.4.4.1—General

Diaphragms, where provided, should be connected to the webs and flanges of all noncomposite box-section members, where practical. The diaphragms shall be designed to resist cross-section distortion of the box and shall be designed to resist torsional moments in the box applied to or resisted at the diaphragm location, and to transmit vertical and lateral forces from the box to the bearings, as applicable.

6.7.4.4.2—Square and Rectangular Hollow Structural Section Members

For all square and rectangular hollow structural section members, placement of diaphragms at the member ends should be considered.

6.7.4.4.3—Welded and Nonwelded Built-Up Noncomposite Box-Section Members

Diaphragms shall be provided within welded and nonwelded built-up noncomposite box-section members at each support and at the ends of the member, unless the ends of the member are connected to other members that serve to retain the shape of the box cross-section. The placement of additional diaphragms at locations of any externally applied concentrated loads shall be considered.

An access hole at least 18.0 in. wide and 24.0 in. high, where practical, should be provided within each internal intermediate diaphragm. Design of the diaphragm shall consider the effect of the access hole on the stresses. Reinforcement around the hole may be required.

Where practical, cross-frames may be used in lieu of diaphragms at locations other than at supports. Connection plates for internal cross-frames shall satisfy the provisions of Article 6.6.1.3.1, as applicable.

In members subject to torsion in which:

C6.7.4.4.1

For welded and nonwelded built-up noncomposite box-section members subject to torsion, cross-sectional distortion stresses are controlled by internal diaphragms or cross-frames. As specified in Article 6.12.2.2.2a, factored transverse plate bending stresses due to cross-section distortion should be limited to 20.0 ksi at the strength limit state in noncomposite box-section members subject to large torques.

C6.7.4.4.2

Holes may be provided in diaphragms of hollow structural section members to accommodate functions such as drainage, hot-dip zinc coating, utilities, and access to connections.

C6.7.4.4.3

Diaphragms acting as flexural members over supports in larger noncomposite box-section members, or when connecting multiple noncomposite box-section members, should also satisfy the applicable requirements of Article 6.7.4.3.

Where practical, access holes in internal intermediate diaphragms should be wide and high enough to allow for convenient maintenance and inspection access. The holes should be placed in the diaphragms in a position that will allow convenient access when passing through the box. Any stiffeners on the diaphragms should be placed back from the edges of the openings.

White et al. (2019b) discuss special moment of inertia requirements for top or bottom struts of internal intermediate cross-frames that serve as transverse stiffeners to enhance the compressive resistance of a longitudinally stiffened plate element.

$$f_{ve} > 0.2\phi_T F_{cv} \quad (6.7.4.4.3-1)$$

where:

- ϕ_T = resistance factor for torsion specified in Article 6.5.4.2
 f_{ve} = factored shear stress due to torsion in the cross-section element under consideration (ksi)
 F_{cv} = nominal shear resistance of the cross-section element under consideration, under shear alone, calculated as specified in Article 6.9.2.2.2 (ksi)

The factored torsional shear stresses, f_{ve} , may be computed using the appropriate equation given in Article C6.9.2.2.2 in lieu of a refined analysis.

The spacing of internal intermediate diaphragms or cross-frames within the member should not exceed 40.0 ft. Internal intermediate diaphragms should be spaced a minimum of 2.0 ft apart.

The recommended minimum spacing of internal intermediate diaphragms is to prevent an inspector from having to straddle two diaphragms at one time.

6.7.4.5—Trusses and Arches

Diaphragms shall be provided at the connections to floorbeams and at other connections or points of application of concentrated loads in truss and arch members. Internal diaphragms may also be provided to maintain member alignment.

Gusset plates engaging a pedestal pin at the end of a truss shall be connected by a diaphragm. The webs of the pedestal should be connected by a diaphragm wherever practical.

If the end of the web plate or cover plate is 4.0 ft or more from the point of intersection of the members, a diaphragm shall be provided between gusset plates engaging main members.

6.7.5—Lateral Bracing

6.7.5.1—General

C6.7.5.1

The need for lateral bracing shall be investigated for all stages of assumed construction procedures and the final condition.

Where required, lateral bracing should be placed either in or near the plane of a flange or chord being braced. Investigation of the requirement for lateral bracing shall include, but not be limited to:

- transfer of lateral wind loads to the bearings as specified in Article 4.6.2.7,
- transfer of lateral loads as specified in Article 4.6.2.8, and
- control of deformations and cross-section geometry during fabrication, erection, and placement of the deck.

Permanent bottom flange lateral bracing members shall be considered to be primary members. Lateral bracing members not required for the final condition

should not be considered to be primary members, and may be removed at the Owner's discretion.

If permanent lateral bracing members are included in the structural model used to determine live load force effects, the force effects in the members shall be computed and considered in the design of the members and their connections for all applicable limit states. The provisions of Articles 6.8.4 and 6.9.3 shall apply.

Connection plates for lateral bracing shall satisfy the requirements specified in Article 6.6.1.3.2.

When lateral bracing is designed for seismic loading, the provisions of Article 4.6.2.8 shall apply.

6.7.5.2—I-Section Members

Continuously braced flanges should not require lateral bracing.

The need for lateral bracing adjacent to supports of I-girder bridges to provide rigidity during construction should be considered.

In I-girder bridges, bottom flange lateral bracing creates a pseudo-closed section formed by the I-girders connected with the bracing and the hardened deck, and therefore becomes load-carrying. Cross-frame forces increase with the addition of bottom flange bracing because the cross-frames act to retain the shape of the pseudo-box section. In addition, moments in the braced girders become more equalized and the bracing members are also subject to significant live load forces.

C6.7.5.2

Wind load stresses in I-sections may be reduced by:

- changing the flange size,
- reducing the diaphragm or cross-frame spacing, or
- adding lateral bracing.

The relative economy of these methods should be investigated.

To help prevent significant relative horizontal movement of the girders in spans greater than 200 ft during construction, it may be desirable to consider providing either temporary or permanent lateral bracing in one or more panels adjacent to the supports of I-girder bridges. For continuous-span bridges, such bracing would only be necessary adjacent to interior supports and should be considered at the free ends of continuous units. Such a system of lateral bracing can also provide a stiffer load path for wind loads acting on the noncomposite structure during construction to help reduce the lateral deflections and flange lateral bending stresses. Top lateral bracing is preferred. Bottom lateral bracing can provide a similar function, but unlike top bracing, would be subject to significant live load forces in the finished structure that would have to be considered.

For horizontally curved bridges, when the curvature is sharp and temporary supports are not practical, it may be desirable to consider providing both top and bottom lateral bracing to ensure pseudo-box action while the bridge is under construction. Top and bottom lateral bracing provides stability to a pair of I-girders.

If temporary lateral bracing is used, the analysis method used must be able to recognize influence of the lateral bracing.

C6.7.5.3

Investigation will generally show that a lateral bracing system is not required between multiple tub sections.

The shear center of an open tub section is located below the bottom flange (Heins, 1975). The addition of top lateral bracing raises the shear center closer to the center of the resulting pseudo-box section, significantly improving the torsional stiffness.

6.7.5.3—Tub-Section Members

For straight girders, and for horizontally curved girders satisfying all the conditions specified in Article 4.6.1.2.4c for neglecting the effects of curvature, a top lateral bracing system should be considered to ensure that deformations of the tub section are adequately controlled and that stability of the tub-section members is provided during erection and placement of the concrete deck. The lateral bracing system may consist of a full-length

lateral bracing system between common flanges of individual tub sections, or a partial-length lateral bracing system consisting of top lateral bracing members between common flanges of individual tub sections extending over 20 to 25 percent of the length of each span at each support end of the girder. If a top lateral bracing system is not provided, or if the top lateral bracing system does not extend for 20 to 25 percent of the length of each span at each support end of the girder, the global stability of the individual noncomposite tub girder shall be investigated for the Engineer's assumed deck placement sequence as specified in Article 6.11.3.2. For horizontally curved girders not satisfying one or more of the conditions specified in Article 4.6.1.2.4c for neglecting the effects of curvature, a full-length lateral bracing system shall be provided.

Top lateral bracing shall be designed to resist shear flow in the pseudo-box section due to the factored loads before the concrete deck has hardened or is made composite. Forces in the bracing due to flexure of the tub shall also be considered during construction based on the Engineer's assumed construction sequence.

If the bracing is attached to the webs, the cross-sectional area of the tub for shear flow shall be reduced to reflect the actual location of the bracing, and a means of transferring the forces from the bracing to the top flange shall be provided.

In addition to resisting the shear flow before the concrete deck has hardened or is made composite, top lateral bracing members are also subject to significant forces due to flexure of the noncomposite tub. In the absence of a more refined analysis, Fan and Helwig (1999) provide an approach for estimating these forces.

Top lateral bracing members are also subject to forces due to wind loads acting on the noncomposite pseudo-box section during construction.

For straight tub girders or horizontally curved tub girders satisfying all the conditions specified in Article 4.6.1.2.4c for neglecting the effects of curvature, top lateral bracing members between the common flanges of the individual tub sections should be provided over 20 to 25 percent of the length of each span at each support end of the girder where the shear deformations are at their maximum (Yura and Widiyanto, 2005) (Armijos-Moya et al., 2019). The need for additional lateral bracing adjacent to lifting points and to resist the shear flow resulting from any net torque on the steel section due to unequal factored deck weight loads acting on each side of the top flanges, or any other known eccentric loads acting on the steel section during construction, should be considered. Cross-section distortion and top-flange lateral bending stresses may need to be considered when a tub with a partial-length bracing system is subjected to a net torque. Section 6.1.1 of Armijos-Moya et al. (2019) provides a suggested procedure for the design of tub girders with a partial-length top lateral bracing system. A full-length lateral bracing system should be considered when the torques acting on the steel section are deemed particularly significant, e.g., tub-section members resting on skewed supports and/or tub-section members on which the deck is unsymmetrically placed in the transverse direction. If a top lateral bracing system is not provided, or if the top lateral bracing system does not extend for 20 to 25 percent of the length of each span at each support end of the girder, the Engineer must ensure the global stability of the individual noncomposite tub girder during the assumed deck placement sequence as specified in Article 6.11.3.2. For cases where a partial-length top lateral bracing system may be deemed impractical, concrete may be placed in the outer 20 to 25 percent of each span and allowed to harden in lieu of top-lateral bracing. However, in such cases, the elastic global lateral-torsional buckling stability of each span of the girder during erection and placement of the concrete in the outer 20 to 25 percent of each span needs to be evaluated.

For both straight and horizontally curved tub sections, a full-length lateral bracing system forms a pseudo-box to help limit distortions brought about by temperature changes occurring prior to concrete deck placement, and to resist the torsion and twist caused by any eccentric loads acting on the steel section during construction. Helwig and Yura (2022) recommend that

diagonal members of the top lateral bracing for tub sections satisfy the following criterion:

$$A_d \geq 0.054w \quad (\text{C6.7.5.3-1})$$

where:

- A_d = minimum required cross-sectional area of one diagonal (in.²)
 w = center-to-center distance between the top of the webs (in.)

Satisfaction of this criterion is intended to ensure that the top lateral bracing will be sized so that the tub will act as a pseudo-box section with minimal warping torsional displacement and normal stresses due to warping torsion less than or equal to ten percent of the major-axis bending stresses. A similar criterion recommending that A_d equal or exceed $0.03w$ was developed assuming tub sections with vertical webs and ratios of section width-to-depth between 0.5 and 2.0, and an X-type top lateral bracing system with the diagonals placed at an angle of 45 degrees relative to the longitudinal centerline of the tub-girder flanges (Heins, 1978). Based on the same assumptions, Eq. C6.7.5.3-1 was derived for single-diagonal top lateral bracing systems, which are more commonly used. In such systems, the angle of the bracing diagonal with respect to the horizontal should not be less than 30 degrees or greater than 60 degrees.

Single-diagonal top lateral bracing systems are preferred over X-type systems because there are fewer pieces to fabricate and erect and fewer connections. However, forces in alternating Warren-type single-diagonal top lateral bracing members, as shown in Figure C6.7.5.3-1, due to flexure of the tub section can sometimes result in the development of significant lateral bending stresses in the top flanges. In lieu of a refined analysis, Fan and Helwig (1999) provide an approach for estimating the top-flange lateral bending stresses due to these forces. If necessary, the flange lateral bending stresses and forces in the diagonal bracing members in this case can often be effectively mitigated by the judicious placement of parallel single-diagonal members, or a Pratt-type configuration, in each bay in lieu of a Warren-type configuration as shown in Figure C6.7.5.3-2; the forces in the struts will typically be larger in the Pratt-type configuration. In the Pratt-type configuration, the members should be oriented based on the sign of the torque so that the forces induced in these members due to torsion offset the compressive or tensile forces induced in the same members due to flexure of the tub section. The forces in the lateral bracing system are very sensitive to the casting sequence. If the member sizes have been optimized based upon an assumed casting sequence, it is imperative that the assumed casting sequence be shown in the contract documents. Field tests have shown that forces in the top lateral system after the deck has been cast are negligible.

6.7.6—Pins

6.7.6.1—Location

Pins should be located so as to minimize the force effects due to eccentricity.

6.7.6.2—Resistance

6.7.6.2.1—Combined Flexure and Shear

Pins subjected to combined flexure and shear shall be proportioned to satisfy:

$$\frac{6.0 M_u}{\phi_f D^3 F_y} + \left(\frac{2.2 V_u}{\phi_v D^2 F_y} \right)^3 \leq 0.95 \quad (6.7.6.2.1-1)$$

where:

D = diameter of pin (in.)
 M_u = moment due to the factored loads (kip-in.)
 V_u = shear due to the factored loads (kip)
 F_y = specified minimum yield strength of the pin (ksi)
 ϕ_f = resistance factor for flexure as specified in Article 6.5.4.2
 ϕ_v = resistance factor for shear as specified in Article 6.5.4.2

The moment, M_u , and shear, V_u , should be taken at the same design section along the pin.

6.7.6.2.2—Bearing

The factored bearing resistance on pins shall be taken as:

$$\left(R_{p^B}\right)_r = \phi_b\left(R_{p^B}\right)_n \quad (6.7.6.2.2-1)$$

in which:

$$(R_{pB})_n = 1.5tDF_y \quad (6.7.6.2.2-2)$$

where:

t = thickness of plate (in.)
 D = diameter of pin (in.)
 ϕ_b = resistance factor for bearing as specified in Article 6.5.4.2

6.7.6.3—Minimum Size Pin for Eyebars

The diameter of the pin, D , shall satisfy:

$$D \geq \left(\frac{3}{4} + \frac{F_y}{400} \right) b \quad (6.7.6.3-1)$$

C6.7.6.2.1

The development of Eq. 6.7.6.2.1-1 is discussed in Kulicki (1983).

C6.7.6.2.2

For the design of new pins subjected to significant rotations, such as for rocker bearings or hinges, the coefficient 1.5 in Eq. 6.7.6.2.2-2 may be halved to 0.75 at the discretion of the Engineer. This accounts for increased wear over the life of pins used for applications with significant rotations. An equivalent approach to that suggested above was used for allowable stress design in the *AASHTO Standard Specifications for Highway Bridges* (2002). For the evaluation of existing pins subjected to significant rotations, the 1.5 coefficient in Eq. 6.7.6.2.2-2 should not be halved.

where:

- F_y = specified minimum yield strength of the eyebar (ksi)
 b = width of the body of the eyebar (in.)

6.7.6.4—Pins and Pin Nuts

Pins shall be of sufficient length to secure a full bearing of all parts connected upon the turned body of the pin. The pin shall be secured in position by:

- hexagonal recessed nuts,
- hexagonal solid nuts with washers, or
- if the pins are bored through, a pin cap restrained by pin rod assemblies.

Pin or rod nuts shall be malleable castings or steel and shall be secured in position by cotter pins through the threads or by burring the threads. Commercially available lock nuts may be used as an alternate to burring the threads or use of cotter pins.

6.7.7—Heat-Curved Rolled Beams and Welded Plate Girders

6.7.7.1—Scope

This Article pertains to rolled beams and constant-depth welded I-section plate girders heat-curved to obtain a horizontal curvature. Structural steels conforming to AASHTO M 270M/M 270 (ASTM A709/A709M), Grades 36, 50, 50S, 50W, HPS 50W, HPS 70W or HPS 100W (Grades 250, 345, 345S, 345W, HPS 345W, HPS 485W or HPS 690W) may be heat-curved.

6.7.7.2—Geometric Limitations

The provisions of Article 14.3.2.2 of the AASHTO *LRFD Steel Bridge Fabrication Specifications* regarding cross-sectional limitations and radius limitations on heat curving shall apply. For each field section of a horizontally curved rolled-beam or welded girder, the Engineer shall indicate on the contract documents whether or not heat curving is permitted according to the specified limitations.

6.7.8—Bent Plates

Structural steel plates and bars that are to be cold or hot bent shall satisfy the requirements for bent plates specified in Section 10 of the AASHTO *LRFD Steel Bridge Fabrication Specifications*.

C6.7.8

Article 10.2 of the AASHTO *LRFD Steel Bridge Fabrication Specifications* limits the minimum bend radius for all grades and thicknesses of steel conforming to AASHTO M 270/M 270 (ASTM A709/A709M), regardless of direction of rolling, to $5.0t$ where t is the thickness of the plate. The radius is measured to the concave face of the plate. For cross-frame or diaphragm connection plates up to 0.75 in., the minimum bending radii may be taken as $1.5t$. If the bend lines for the connection plates are parallel to the direction of final rolling, the minimum bend radius is to be increased to $2.25t$. These limits are to ensure that the bending of the plate has not significantly lowered the toughness and ductility of the plate. Smaller radius bends may be used with the approval of the Engineer.

6.8—TENSION MEMBERS**6.8.1—General**

Members and splices subjected to axial tension shall be investigated for:

- yield on the gross section using Eq. 6.8.2.1-1 and
- fracture on the net section using Eq. 6.8.2.1-2.

Holes larger than those typically considered for connectors such as bolts shall be deducted in determining the gross section area.

The determination of the net section shall require consideration of:

- the gross area from which deductions will be made or reduction factors applied, as appropriate;
- deductions for all holes in the design cross-section; correction of the bolt hole deductions for the stagger rule specified in Article 6.8.3;
- application of the reduction factor, U , specified in Article 6.8.2.2 for members and Article 6.13.5.2 for splice plates and other splicing elements to account for shear lag; and
- application of the 85-percent maximum area efficiency factor for splice plates and other splicing elements specified in Article 6.13.5.2.

Tension members shall satisfy the slenderness requirements specified in Article 6.8.4 and the fatigue requirements of Article 6.6.1. Block shear strength shall be investigated at end connections as specified in Article 6.13.4.

C6.8.1

Holes typically deducted where determining the gross section include pin holes, access holes, and perforations.

6.8.2—Tensile Resistance

6.8.2.1—General

The factored tensile resistance, P_r , shall be taken as the lesser of the values given by Eqs. 6.8.2.1-1 and 6.8.2.1-2.

$$P_r = \phi_y P_{ny} = \phi_y F_y A_g \quad (6.8.2.1-1)$$

$$P_r = \phi_u P_{nu} = \phi_u F_u A_n R_p U \quad (6.8.2.1-2)$$

where:

- P_{ny} = nominal tensile resistance for yield on the gross section (kip)
- P_{nu} = nominal tensile resistance for fracture on the net section (kip)
- F_y = specified minimum yield strength (ksi)
- A_g = gross cross-sectional area of the member (in.²)
- F_u = tensile strength (ksi)
- A_n = net area of the member as specified in Article 6.8.3 (in.²)
- R_p = reduction factor for holes taken equal to 0.90 for bolt holes punched full size and 1.0 for bolt holes drilled full size or subpunched and reamed to size
- U = reduction factor to account for shear lag; 1.0 for components in which force effects are transmitted to all elements, and as specified in Article 6.8.2.2 for other cases
- ϕ_y = resistance factor for yielding of tension members as specified in Article 6.5.4.2
- ϕ_u = resistance factor for fracture of tension members as specified in Article 6.5.4.2

6.8.2.2—Reduction Factor, U

The shear lag reduction factor, U , shall be used when investigating the tension fracture check specified in Article 6.8.1 at the strength limit state.

In the absence of more refined analysis or tests, the reduction factors specified herein may be used to account for shear lag in connections.

The shear lag reduction factor, U , may be calculated as specified in Table 6.8.2.2-1. For open cross-section members, the calculated value of U should not be taken to be less than the ratio of the gross area of the connected element or elements to the member gross area.

C6.8.2.1

The reduction factor, U , does not apply when checking yielding on the gross section because yielding tends to equalize the nonuniform tensile stresses caused over the cross-section by shear lag. The reduction factor, R_p , conservatively accounts for the reduced fracture resistance in the vicinity of bolt holes that are punched full size (Brown et al., 2007). No reduction in the net section fracture resistance is required for holes that are drilled full size or subpunched and reamed to size. The reduction in the factored resistance for punched holes was previously accounted for by increasing the hole size for design by 0.0625 in., which penalized drilled and subpunched and reamed holes and did not provide a uniform reduction for punched holes since the reduction varied with the hole size.

Due to strain hardening, a ductile steel loaded in axial tension can resist a force greater than the product of its gross area and its yield strength prior to fracture. However, excessive elongation due to uncontrolled yielding of gross area not only marks the limit of usefulness but it can precipitate failure of the structural system of which it is a part. Depending on the ratio of net area to gross area and the mechanical properties of the steel, the component can fracture by failure of the net area at a load smaller than that required to yield the gross area. General yielding of the gross area and fracture of the net area both constitute measures of component strength. The relative values of the resistance factors for yielding and fracture reflect the different reliability indices deemed proper for the two modes.

The part of the component occupied by the net area at fastener holes generally has a negligible length relative to the total length of the member. As a result, the strain hardening is quickly reached and, therefore, yielding of the net area at fastener holes does not constitute a strength limit of practical significance, except perhaps for some built-up members of unusual proportions.

For welded connections, A_n is the gross section less any access holes in the connection region.

C6.8.2.2

The provisions of Article 6.8.2.2 are adapted from AISC *Specification*, Section D3, Effective Net Area for design of tension members (2022b). These provisions specify that for open cross-section members, such as W, M, S, C, or HP shapes, tees, and single and double angles, the calculated value of U should not be taken to be less than the ratio of the gross area of the connected element or elements to the member gross area. The preceding provision does not apply to closed sections, such as HSS, nor to plates.

The effect of the moment due to the eccentricities in the connection in angle members and light structural tee

members loaded eccentrically in axial tension may be ignored in the design of the member and the connections (AISC, 2022b); the effect of the connection eccentricity is addressed through the use of the shear lag reduction factor, U .

Examples of the distances $\bar{x}$ and L used in the calculation of the reduction factor, U , for all types of tension members, except plates and hollow structural section members, are illustrated in Figure C6.8.2.2-1.

Table 6.8.2.2-1—Shear Lag Factors for Connections to Tension Members

Case	Description of Element		Shear Lag Factor, U	Example
1	All tension members where the tension load is transmitted directly to each of cross-sectional elements by fasteners or welds (except as in Cases 4, 5, and 6).		$U=1.0$	—
2	All tension members, except plates and HSS, where the tension load is transmitted to some but not all of the cross-sectional elements by fasteners or longitudinal welds or by longitudinal welds in combination with transverse welds. For longitudinal welds with unequal lengths, the average length of the longitudinal welds shall be used for L . (Alternatively, Case 7 is permitted to be used for W, M, S, and HP shapes, and Case 8 is permitted to be used for angles.)		$U = 1 - \frac{\bar{x}}{L}$	
3	All tension members where the tension load is transmitted only by transverse welds to some but not all of the cross-sectional elements.		$U=1.0$ and A_n = area of the directly connected elements	—
4	Plates where the tension load is transmitted by longitudinal welds only. See Case 2 for definition of $\bar{x}$. L shall not be less than four times the weld size. For longitudinal welds with unequal lengths, the average length of the longitudinal welds shall be used for L ; the length of each weld shall not be less than four times the weld size.		$U = \frac{3L^2}{3L^2 + w^2} \left(1 - \frac{\bar{x}}{L} \right)$	
5	Round HSS with a single concentric gusset plate through slots in the hollow structural section.		$L \geq 1.3D \dots U=1.0$ $D \leq L < 1.3D \dots U = 1 - \frac{\bar{x}}{L}$ $\bar{x} = \frac{D}{\pi}$	
6	Rectangular HSS	with a single concentric gusset plate	$L \geq H \dots U = 1 - \frac{\bar{x}}{L}$ $\bar{x} = \frac{B^2 + 2BH}{4(B + H)}$	
		with two side gusset plates	$L \geq H \dots U = 1 - \frac{\bar{x}}{L}$ $\bar{x} = \frac{B^2}{4(B + H)}$	
7	W, M, S, or HP shapes or tees cut from these shapes (If U is calculated per Case 2, the larger value is permitted to be used.)	with flange connected with three or more fasteners per line in the direction of loading	$b_f \geq \frac{2}{3}d \dots U = 0.90$ $b_f < \frac{2}{3}d \dots U = 0.85$	—
		with web connected with four or more fasteners per line in the direction of loading	$U=0.70$	—
8	Single and double angles (If U is calculated per Case 2, the larger value is permitted to be used.)	with four or more fasteners per line in the direction of loading	$U=0.80$	—
		with three fasteners per line in the direction of loading (with fewer than three fasteners per line in the direction of loading, use Case 2)	$U=0.60$	—

where:

 L = length of connection (in.) w = plate width (in.)

- $\bar{x}$ = connection eccentricity (in.)
 B = overall width of rectangular hollow structural section member, measured 90 degrees to the plane of the connection (in.)
 D = outside diameter of round hollow structural section member (in.)
 H = overall height of rectangular hollow structural section member, measured in the plane of the connection (in.)
 d = full nominal depth of the section; for tees, depth of the section from which the tee was cut (in.)
 b_f = flange width (in.)

Figure C6.8.2.2-1—Determination of $\bar{x}$ and L in the Calculation of the Shear Lag Reduction Factor, U

$$\left(\frac{M_{ux}}{M_{rx}} + \frac{M_{uy}}{M_{ry}} \right) \leq 1.0 \quad (6.8.2.3.1-4)$$

where:

- P_{ry} = factored tensile resistance based on tension yielding, obtained from Eq. 6.8.2.1-1 (kip)
- P_u = factored tensile axial force (kip)
- M_{rx} = factored flexural resistance about the x -axis taken as ϕ_f times the nominal flexural resistance about the x -axis determined as specified in Article 6.10, 6.11, or 6.12, as applicable, excluding tension-flange rupture (kip-in.)
- M_{rxc} = factored flexural resistance about the x -axis taken as ϕ_f times the nominal flexural resistance about the x -axis considering compression buckling, determined as specified in Article 6.10 or 6.12, as applicable (kip-in.)
- M_{rxpe} = for I-section members, ϕ_f times the plastic moment about the x -axis neglecting any web longitudinal stiffeners; for noncomposite box-section members, ϕ_f times the effective plastic moment about the x -axis, based on the effective compression flange area as defined in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable, and neglecting any web longitudinal stiffeners (kip-in.)
- M_{ry} = factored flexural resistance about the y -axis taken as ϕ_f times the nominal flexural resistance about the y -axis determined as specified in Article 6.12, as applicable, excluding tension-flange rupture (kip-in.)
- M_{ryc} = factored flexural resistance about the y -axis taken as ϕ_f times the nominal flexural resistance about the y -axis considering compression buckling, determined as specified in Article 6.12, as applicable; $M_{ryc} = M_{ryt} = M_{ry}$ for I-section members (kip-in.)
- M_{rype} = for I-section members, ϕ_f times the plastic moment about the weak axis; for noncomposite box-section members, ϕ_f times the effective plastic moment about the y -axis, based on the effective compression flange area as defined in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable, and neglecting any web longitudinal stiffeners (kip-in.)
- M_{ux}, M_{uy} = factored moments about the x - and y -axes, respectively (kip-in.)
- ϕ_f = resistance factor for flexure specified in Article 6.5.4.2

For all cross-section plate elements that are supported along two longitudinal edges and are slender as defined in Article 6.9.4.2.2a, and for slender panels of

When M_{rx} is influenced by LTB, M_{ux}/M_{rx} depends on the overall length effects associated with the LTB strength limit state. Therefore, in this case, Eqs. 6.8.2.3.1-1 and 6.8.2.3.1-2 are not cross-section resistance checks. Hence, the largest value of M_{ux}/M_{rx} associated with the unbraced length relevant to the LTB resistance should be considered along with the other cross-section based values of M_{uy}/M_{ry} and P_u/P_{ry} . That is, when M_{rx} is governed by LTB, there is one M_{ux}/M_{rx} value for a given unbraced length that may be combined with the individual cross-section based M_{uy}/M_{ry} and P_u/P_{ry} values. Furthermore, one should recognize that the largest value of M_{ux}/M_{rx} does not necessarily occur for the load combination that gives the largest value of M_{ux} , as discussed in Article C6.9.2.2.1.

Considering the above attributes, the largest M_{ux}/M_{rx} associated with the unbraced length relevant to the LTB resistance may be combined conservatively with the largest M_{uy}/M_{ry} and P_u/P_{ry} values along this length in evaluating Eqs. 6.8.2.3.1-1 and 6.8.2.3.1-2.

When M_{rx} is governed by a limit state other than LTB, all the resistance terms in Eqs. 6.8.2.3.1-1 and 6.8.2.3.1-2 are cross-section based, and therefore, these equations may be evaluated on a cross-section by cross-section basis along the member length. The Engineer is referred to Article C6.9.2.2.1 for a more detailed discussion of when cross-section by cross-section based evaluation of strength interaction equations is and is not appropriate.

Eqs. 6.8.2.3.1-3 and 6.8.2.3.1-4 define the strength interaction curve shown in Figure C6.8.2.3.1-2, which conservatively recognizes that axial tension tends to have a negligible to beneficial impact on the flexural resistances associated with compression buckling; therefore, the unity check value from the compression-buckling-based strength interaction equation, Eq. 6.8.2.3.1-4, need not consider the influence of the axial tension. Eq. 6.8.2.3.1-4 limits the flexural resistances to a linear interaction between M_{rxc} and M_{ryc} . The flexural resistance is not reduced below that associated with Eq. 6.8.2.3.1-4 until a linear interaction between the yield load in tension, P_{ry} , and the corresponding plastic moments, M_{rxpe} or M_{rype} , is reached according to Eq. 6.8.2.3.1-3. For doubly symmetric I-section members, Eqs. 6.8.2.3.1-3 and 6.8.2.3.1-4 provide an accurate to conservative representation of the C_b modifier effect defined in Section H1.2 of AISC (2022b).

When Eq. 6.8.2.3.1-3 is employed, all of the resistance terms are cross-section based, and therefore, this equation may be checked on a cross-section by cross-section basis along the length. However, when Eq. 6.8.2.3.1-4 is employed and M_{rxc} is influenced by LTB, the above discussion pertaining to M_{rx} applies; hence, the largest value of M_{ux}/M_{rxc} associated with the length

longitudinally stiffened plates as defined in Article E6.1.2, the provisions of Article 6.9.4.5 also shall be satisfied.

relevant to the LTB resistance should be considered along with the other cross-section based values of M_u/M_{ryc} along this length.

Figure C6.8.2.3.1-2—Interaction between Axial Tension and Compression, Flexural Yielding and Buckling in Flexural Compression Corresponding to Eqs. 6.8.2.3.1-3 and 6.8.2.3.1-4

For information on computing the factored flexural resistances in terms of stress about the x - and y -axes, and further discussion of the proper application of these equations, refer to Articles 6.9.2.2.1 and C6.9.2.2.1.

6.8.2.3.2—Interaction with Torsional and/or Flexural Shear

For the following member types:

- noncomposite rectangular box-section members, including square and rectangular HSS, and
- noncomposite circular tubes, including round HSS,

when the member is subjected to torsion resulting in a maximum ratio of the factored torsional shear stress to the corresponding cross-section element factored shear resistance, $f_{ve}/\phi_T F_{cv}$, greater than 0.2, the factored torsional shear stresses shall be considered within the applicable strength interaction equations as specified herein.

For general members, including those specified above, where P_u/P_{ry} is greater than 0.05, the factored flexural shear stresses shall be considered within the applicable strength interaction equations as specified

C6.8.2.3.2

The factored torsional shear stresses in the cross-section element under consideration for use in the computation of Δ , Δ_x , and Δ_y may be computed using the equations given in Article C6.9.2.2.2 in lieu of a refined analysis.

herein; otherwise, the factored flexural shear stresses need not be considered.

Where the consideration of both the torsional and flexural shear stresses is required, the torsional and flexural shear stresses shall be summed based on their corresponding directions in each of the plate elements of the cross-section, given the internal loadings. Where either of the above exclusion conditions are met, the corresponding contributions to the shear stresses shall be taken as zero. When the corresponding flexural shear, torsional shear and/or combined shear stress, as applicable, is nonzero:

- P_{ry} shall be multiplied by Δ ,
- M_{rx} , M_{rxc} and M_{rxpe} shall be multiplied by Δ_x , and
- M_{ry} , M_{ryc} and M_{rype} shall be multiplied by Δ_y ,

in Eqs. 6.8.2.3.1-1 through 6.8.2.3.1-4. ϕ_T is the resistance factor for torsion specified in Article 6.5.4.2. Δ , Δ_x , Δ_y , and F_{cv} shall be computed as specified in Article 6.9.2.2.2.

For elements of noncomposite rectangular box-section members, including square and rectangular HSS, the smallest value of Δ determined for each of the cross-section elements shall be used for Δ , the smallest Δ_x value from the two flange elements of the cross-section parallel to the x -axis and contributing to M_{rx} shall be used for Δ_x , and the smallest Δ_y value from the two flange elements of the cross-section parallel to the y -axis and contributing to M_{ry} shall be used for Δ_y .

For noncomposite circular tubes, including round HSS, only one calculation of Δ is required, based on the cross-section torque and/or the vector combination of the cross-section shears V_{ux} and V_{uy} , and this Δ shall be applied to each of the terms in the applicable member strength interaction equation.

For I-section members, the cross-section shear stresses due to torque shall be neglected. For these member types, Δ_x and Δ_y shall be taken equal to 1.0 in all cases, and the only the flexural shear stresses in the web shall be considered in the calculation of Δ .

6.8.2.3.3—Tension Rupture under Axial Tension or Compression Combined with Flexure

C6.8.2.3.3

The following locations:

- Cross-sections containing bolt holes in one or more flanges that are subjected to tension under combined axial tension or compression and flexure at connection or nonconnection locations,
- Cross-sections at connection or nonconnection locations subjected to axial tension and flexure and containing bolt holes in other cross-section elements, or

Eq. 6.8.2.3.3-1 addresses the strength interaction between flexure and axial tension or compression pertaining to tension rupture at the locations listed. This equation focuses on the specific axial force, tension or compression, combined with the specific moment at the cross-section under consideration. The axial strength ratio term is negative in Eq. 6.8.2.3.3-1, causing a beneficial subtractive effect, when the cross-section having the bolt holes is subjected to axial compression. The axial strength ratio term is positive, causing an additive effect, when the cross-section is subjected to axial tension. This Article is a generalization of Section

- Cross-sections at welded connections subjected to axial tension and flexure,

shall satisfy:

$$\frac{P_u}{P_r} + \frac{M_u}{M_r} \leq 1.0 \quad (6.8.2.3.3-1)$$

in which:

M_r = factored tension rupture flexural resistance about the axis of bending under consideration (kip-in.)

$$= 0.84 \left(\frac{A_{nf}}{A_{gf}} \right) F_u S_t \leq F_{yt} S_t \quad (6.8.2.3.3-2)$$

where:

A_{nf} = net area of the tension flange determined as specified in Article 6.8.3; for sections not containing a flange loaded in flexural tension, and for sections at welded connections, A_{nf}/A_{gf} shall be taken equal to 1.0 (in.²)

A_{gf} = gross area of the tension flange; for sections not containing a flange loaded in flexural tension, and for sections at welded connections, A_{nf}/A_{gf} shall be taken equal to 1.0 (in.²)

F_u = specified minimum tensile strength determined as specified in Table 6.4.1-1 of the cross-section element under consideration (ksi)

F_{yt} = specified minimum yield strength of the cross-section element under consideration (ksi)

S_t = minimum elastic section modulus of the gross cross-section about the axis of bending under consideration (in.³)

M_u = factored moment about the principal axis of bending under consideration at the cross-section under consideration; positive for tension and negative for compression in the cross-section element under consideration (kip-in.)

P_r = for cross-sections subjected to axial tension, factored tensile rupture resistance of the net section based on Eq. 6.8.2.1-2; for cross-sections subjected to axial compression, factored tensile yield resistance of the cross-section based on Eq. 6.8.2.1-1 (kip)

P_u = maximum factored axial force at the cross-section under consideration, positive in tension and negative in compression (kip)

H4 of AISC (2022b), including the handling of tension flanges with holes in flexural members as specified in Article 6.10.1.8. The variable, S_t , is taken conservatively as the minimum elastic section modulus as in AISC (2022b).

Angle members and light structural tee members loaded eccentrically in axial tension are to be designed only for axial tension; the moment effects due to connection eccentricities are addressed in the calculation of the shear lag reduction factor, U , in Article 6.8.2.2.

Each flange subjected to tension due to combined axial force and flexure shall be checked separately; otherwise, only the point on the cross-section subjected to maximum tension due to combined axial force and flexure shall be checked. The moment, M_u , shall be

6.8.5—Built-Up Members**6.8.5.1—General**

The main elements of tension members built up from rolled or welded shapes shall be connected by continuous plates with or without perforations or by tie plates with or without lacing. Welded connections between shapes and plates shall be continuous. Bolted connections between shapes and plates shall conform to the provisions of Article 6.13.2.

C6.8.5.1

Perforated plates, rather than tie plates and/or lacing, are now used almost exclusively in built-up members. However, tie plates with or without lacing may be used where special circumstances warrant. Limiting design proportions are given in AASHTO *Standard Specifications for Highway Bridges* (2002) and AISC (2022b).

6.8.5.2—Perforated Plates

The ratio of length in the direction of stress to width of holes shall not exceed 2.0.

The clear distance between holes in the direction of stress shall not be less than the transverse distance between the nearest line of connection bolts or welds. The clear distance between the end of the plate and the first hole shall not be less than 1.25 times the transverse distance between bolts or welds.

The periphery of the holes shall have a minimum radius of 1.5 in.

The unsupported widths at the edges of the holes may be assumed to contribute to the net area of the member. Where holes are staggered in opposite perforated plates the net area of the member shall be considered the same as for a section having holes in the same transverse plane.

6.8.6—Eyebars**6.8.6.1—Factored Resistance**

The factored resistance of the body of the eyobar shall be taken as specified in Eq. 6.8.2.1-1.

C6.8.6.1

Eq. 6.8.2.1-2 does not control because the net section in the head is at least 1.35 greater than the section in the body.

6.8.6.2—Proportions**C6.8.6.2**

Eyebars shall have a uniform thickness not less than 0.5 in. or more than 2.0 in.

The transition radius between the head and the body of an eyobar shall not be less than the width of the head at the centerline of the pin hole.

The net width of the head at the centerline of the pin hole shall not be less than 135 percent the required width of the body.

The net dimension of the head beyond the pin hole taken in the longitudinal direction shall not be less than 75 percent of the width of the body.

The width of the body shall not exceed eight times its thickness.

The center of the pin hole shall be located on the longitudinal axis of the body of the eyobar. The pin-hole diameter shall not be more than 0.03125 in. greater than the pin diameter.

For steels having a specified minimum yield strength greater than 70 ksi, the hole diameter shall not exceed five times the eyebar thickness.

6.8.6.3—Packing

The eyebars of a set shall be symmetrical about the central plane of the member and as parallel as practicable. They shall be restrained against lateral movement on the pins and against lateral distortion due to the skew of the bridge.

The eyebars shall be so arranged that adjacent bars in the same panel will be separated by at least 0.5 in. Ring-shaped spacers shall be provided to fill any gaps between adjacent eyebars on a pin. Intersecting diagonal bars that are not sufficiently spaced to clear each other at all times shall be clamped together at the intersection.

6.8.7—Pin-Connected Plates

6.8.7.1—General

Pin-connected plates should be avoided wherever possible.

The provisions of Article 6.8.2.1 shall be satisfied.

6.8.7.2—Pin Plates

The factored bearing resistance on pin and main plates, P_r , shall be taken as:

$$P_r = \phi_b P_n = \phi_b A_b F_y \quad (6.8.7.2-1)$$

where:

- P_n = nominal bearing resistance (kip)
- A_b = projected bearing area on the plate (in.²)
- F_y = specified minimum yield strength of the plate (ksi)
- ϕ_b = resistance factor for bearing, specified in Article 6.5.4.2

The main plate may be strengthened in the region of the hole by attaching pin plates to increase the thickness of the main plate.

If pin plates are used, they shall be arranged to minimize load eccentricity and shall be attached to the main plate by sufficient welds or bolts to transmit the bearing forces from the pin plates into the main plate.

6.8.7.3—Proportions

The combined net area of the main plate and pin plates on a transverse cross-section through the centerline

The limitation on the hole diameter for steel with specified minimum yield strengths above 70 ksi, which is not included in the AASHTO *Standard Specifications for Highway Bridges* (2002), is intended to prevent dishing beyond the pin hole (AISC, 2022b).

C6.8.6.3

The eyebar assembly should be detailed to prevent corrosion-causing elements from entering the joints.

Eyebars sometimes vibrate perpendicular to their plane. The intent of this provision is to prevent repeated eyebar contact by providing adequate spacing or by clamping.

C6.8.7.3

The proportions specified in this Article assure that the member will not fail in the region of the hole if the

of the pin hole shall not be less than 1.4 times the required net area of the main plate away from the hole.

The combined net area of the main plate and pin plates beyond the pin hole taken in a longitudinal direction shall not be less than the required net area of the main plate away from the pin hole.

The center of the pin hole shall be located on the longitudinal axis of the main plate. The pin hole diameter shall not be more than 0.03125 in. greater than the pin diameter.

For steels having a specified minimum yield strength greater than 70.0 ksi, the hole diameter shall not exceed five times the combined thickness of the main plate and pin plates.

The combined thickness of the main plate and pin plates shall not be less than 12 percent of the net width from the edge of the hole to the edge of the plate or plates. The thickness of the main plate shall not be less than 12 percent of the required width away from the hole.

6.8.7.4—Packing

Pin-connected members shall be restrained against lateral movement on the pin and against lateral distortion due to the skew of the bridge.

6.9—COMPRESSION MEMBERS

6.9.1—General

The provisions of this Article shall apply to prismatic noncomposite and composite steel members subjected to either axial compression or combined axial compression and flexure.

Arches shall also satisfy the requirements of Article 6.14.4.

Compression chords of half through-trusses shall also satisfy the requirements of Article 6.14.2.9.

6.9.2—Compressive Resistance

6.9.2.1—Axial Compression

The factored resistance of components in compression, P_r , shall be taken as:

$$P_r = \phi_c P_n \quad (6.9.2.1-1)$$

where:

P_n = nominal compressive resistance, as specified in Articles 6.9.4 or 6.9.5, as applicable (kip)

ϕ_c = resistance factor for compression, as specified in Article 6.5.4.2

strength limit state is satisfied in the main plate away from the hole.

C6.8.7.4

The pin-connected assembly should be detailed to prevent corrosion-causing elements from entering the joints.

C6.9.1

Conventional column design formulas contain allowances for imperfections and eccentricities permissible in normal fabrication and erection. The effect of any significant additional eccentricity should be accounted for in bridge design.

6.9.2.2—Combined Axial Compression, Flexure, and Flexural and/or Torsional Shear

6.9.2.2.1—General

Except as permitted otherwise in Articles 6.9.4.4 and 6.9.6.3, the factored moments, M_{ux} and M_{uy} , and factored axial compressive load, P_u , calculated by elastic analysis shall satisfy the following relationships, as applicable, with all ratios taken as positive:

- For members in which all of the cross-section elements are defined as compact for flexure according to the provisions of Articles A6.2.1, A6.3.2, 6.11.6.2.2, and 6.12.2.2.2c, as applicable:

- If $\frac{P_u}{P_r} < 0.2$, then

$$\frac{P_u}{2P_r} + \left(\frac{M_{ux}}{M_{rx}} + \frac{M_{uy}}{M_{ry}} \right) \leq 1.0 \quad (6.9.2.2.1-1)$$

- If $\frac{P_u}{P_r} \geq 0.2$, then

$$\frac{P_u}{P_r} + \frac{8}{9} \left(\frac{M_{ux}}{M_{rx}} + \frac{M_{uy}}{M_{ry}} \right) \leq 1.0 \quad (6.9.2.2.1-2)$$

- The following may be employed for all types of members:

$$\frac{P_u}{P_r} + \frac{M_{ux}}{M_{rx}} + \frac{M_{uy}}{M_{ry}} \leq 1.0 \quad (6.9.2.2.1-3)$$

where:

- P_r = factored compressive resistance as specified in Article 6.9.2.1 (kip)
- P_u = factored compressive axial force (kip)
- M_{rx} = factored flexural resistance about the x -axis taken equal to ϕ_f times the nominal flexural resistance about the x -axis determined as specified in Article 6.10, 6.11, or 6.12, as applicable, excluding tension-flange rupture (kip-in.)
- M_{ry} = factored flexural resistance about the y -axis taken equal to ϕ_f times the nominal flexural resistance about the y -axis determined as specified in Article 6.12, as applicable, excluding tension-flange rupture (kip-in.)

C6.9.2.2

These provisions address the strength interaction for any combination of axial compression, uniaxial or biaxial flexure, and flexural and/or torsional shear, including combinations where one or more of the individual actions may be zero.

C6.9.2.2.1

Interaction equations in members subjected to axial tension or compression in combination with other loading effects generally involve significant design simplification. Such equations involving exponents of 1.0 on the moment ratios are often conservative. More exact, nonlinear interaction curves are available and are discussed in Ziemian (2010). If these interaction equations are used, additional investigation of service limit state stresses may be necessary to avoid premature yielding.

Eqs. 6.9.2.2.1-1 and 6.9.2.2.1-2 are identical to Eqs. (H1-1a) and (H1-1b) of AISC (2022b). They were selected for use in that Specification after being compared with a number of alternative formulations considering the results from refined inelastic analyses of 82 frame sidesway cases (Kanchanalai, 1977) involving rolled wide-flange section members. The strength envelope represented by these equations is similar to that shown for the axial tension and biaxial bending case in Figure C6.8.2.3.1-1. Eqs. 6.9.2.2.1-1 and 6.9.2.2.1-2 provide an accurate to conservative approximation of the resistances under combined loading for members in which all the cross-section elements are compact. Such members are potentially able to develop significant distributed yielding within their cross-sections for small axial load and dominant flexural loading. As such, these types of members are able to develop a “knee” in the interaction curve between their flexural and axial compressive resistances. Members with other cross-section types generally have limited capability to develop such a “knee.”

For members where Eqs. 6.9.2.2.1-1 and 6.9.2.2.1-2 apply, the member ultimate resistances tend to involve extensive yielding in both tension and compression. For other member types, the member strength interaction is usually governed by additive compression buckling effects from axial compression and flexure, which are captured accurately to conservatively by the linear interaction Eq. 6.9.2.2.1-3.

The strength interaction between flexure and axial tension or compression pertaining to tension-flange rupture at a cross-section containing holes in the tension flange is addressed in Article 6.8.2.3.3. Article 6.8.2.3.3 provides a separate linear interaction equation focusing on the specific axial force combined with the specific moment causing the flexural tension in the flange at a given cross-section.

ϕ_f = resistance factor for flexure specified in Article 6.5.4.2

The moments, M_{ux} and M_{uy} , shall be determined by:

- a second-order elastic analysis that accounts for the magnification of moment caused by the factored axial load, or
- the approximate single-step adjustment method specified in Article 4.5.3.2.2b, or a comparable amplification factor-based procedure.

For sections where the nominal flexural resistance about the major axis of the section is expressed in terms of stress, the factored flexural resistance about that axis in Eqs. 6.9.2.2.1-1 through 6.9.2.2.1-3 should be taken as:

$$M_{rx} = \text{the smaller of } \phi_f F_{nc} S_{xc} \text{ and } \phi_f F_{nt} S_{xt} \quad (6.9.2.2.1-4)$$

where:

S_{xt} = elastic section modulus about the major axis of the section to the tension flange taken as M_{yt}/F_{yt} (in.³)

For sections where the nominal flexural resistance about the major axis of the section is determined according to the provisions of Appendix A6, the factored flexural resistance about that axis in Eqs. 6.9.2.2.1-1 through 6.9.2.2.1-3 should be taken as:

$$M_{rx} = \text{the smaller of } \phi_f M_{nc} \text{ and } \phi_f M_{nt} \quad (6.9.2.2.1-5)$$

where:

M_{nc} = nominal flexural resistance based on the compression flange (kip-in.)

P_u , M_{ux} , and M_{uy} are concurrent factored axial and flexural forces determined from a structural analysis. The cross-sections exhibiting the maximum strength ratios generally are located at different positions along the member unbraced lengths. The beam-column strength interaction equations generally are not intended to be applied on a cross-section by cross-section basis along the member length, where typically only one of the strength ratios is maximum at a given cross-section, and the other ratios are at their nonmaximum values. The cross-section by cross-section approach to evaluating the strength interaction is appropriate only when: 1) all of the flexural strength ratios are cross-section based, e.g., when all M_{uy}/M_{ry} values are combined with M_{ux}/M_{rx} values that are based on either flange local buckling (FLB), tension-flange yielding, or the plateau strength in LTB; and 2) the member is prismatic and the axial force P_u is constant along the length such that P_u/P_r is a constant value along the member length. The axial compressive strength ratio, P_u/P_r , and the LTB strength ratio, M_{ux}/M_{rx} , when M_{rx} is less than the plateau strength, depend on the overall length effects associated with the corresponding stability behavior. These strength ratios are not cross-section limit states checks. Hence, performing the member strength interaction checks on a cross-section by cross-section basis with the equations provided in this Article is generally unconservative unless the above conditions are satisfied.

When P_u and/or M_{ux} vary along the member length, the appropriate resistance terms in the strength ratios P_u/P_r and/or M_{ux}/M_{rx} at a given cross-section should be the value of the axial load and/or the major-axis bending moment at that cross-section when the overall member resistance is reached within the corresponding buckling mode. These separate maximum strength ratios along the member unbraced length are then combined together in the member strength interaction checks. If P_u varies along the length relevant to the governing buckling mode, it is common to determine P_r based on the assumption of constant axial compression and to use the largest value of P_u along this length in determining P_u/P_r . More rigorously, the buckling resistance P_r can be determined as the internal axial force at a given cross-section at overall buckling of the member, considering the influence of the variation of the axial force along the member length, and the corresponding P_u at this cross-section can be divided by this P_r to obtain the governing strength ratio (White and Jeong, 2019). This more rigorous approach can also capture the influence of nonprismatic member geometry. This approach, along with the potentially beneficial influence of continuity effects and interaction buckling effects between the adjacent unbraced lengths, is discussed further in White and Jeong (2019).

In lieu of a more refined analysis, when considering the strength interaction at a given cross-section, the maximum P_u/P_r and the maximum M_{ux}/M_{rx} values throughout the length relevant to the governing buckling modes should be used along with any cross-section based

M_{nt} = nominal flexural resistance based on the tension flange (kip-in.)

Interaction with torsional and/or flexural shear, as applicable, shall be considered as specified in Article 6.9.2.2.2.

For all cross-section plate elements that are supported along two longitudinal edges and are slender as defined in Article 6.9.4.2.2a, and for slender panels of longitudinally stiffened plates as defined in Appendix E6.1.2, the provisions of Article 6.9.4.5 also shall be satisfied.

M_{ux}/M_{rx} and M_{uy}/M_{ry} values. As a simplification, the Engineer can combine the maximum P_u/P_r , M_{ux}/M_{rx} and M_{uy}/M_{ry} values throughout each of the smaller of the unbraced lengths ℓ_x , ℓ_y , ℓ_z , i.e., the respective column buckling unbraced lengths, and/or L_b , i.e., the LTB unbraced lengths, for a given location along the overall member length when evaluating the strength interaction equations. This accounts for the stability interactions between responses that are maximum at different cross-sections along the member length, while recognizing that, if say the largest P_u/P_r and/or M_{ux}/M_{rx} values are located at positions far removed from each other, i.e., at positions farther apart than the smaller of ℓ_x , ℓ_y , ℓ_z , and/or L_b , or from other cross-section based M_{ux}/M_{rx} or M_{uy}/M_{ry} values being applied within the strength interaction checks, the combination of these maximum values in the strength interaction is conservative. The physical beam column experiences all of these effects together, and the only way of determining the true interaction between these effects is to employ some type of advanced analysis method that considers them together within a consistent mechanics-based context, as discussed briefly in Article C6.1.

In addition to properly considering the length effects associated with P_u/P_r and M_{ux}/M_{rx} as discussed above, it is important to note that, due to the influence of the moment-gradient factor, C_b , on the LTB resistance, it is possible that a load combination with a major-axis bending moment smaller than the maximum M_{ux} value for the relevant load combinations under consideration can have a larger strength ratio M_{ux}/M_{rx} than the load combination corresponding to the largest M_{ux} . When evaluating the various load combinations for a given design, the concurrent loadings for the load combination having the largest M_{ux}/M_{rx} must be checked. The maximums of each of the strength ratios P_u/P_r , M_{ux}/M_{rx} , and M_{uy}/M_{ry} from all relevant load combinations may be summed conservatively to evaluate the resistance under the combined loading.

S_{xc} and S_{xt} are defined in Eq. 6.9.2.2.1-4 as equivalent values that account for the combined effects of the loads acting on different sections in composite members.

For I- and H-shaped sections, the nominal flexural resistance about an axis parallel to the web is determined according to the provisions of Article 6.12.2.2.1.

For tees and double angles subject to combined axial compression and flexure in which the axial and flexural stresses in the flange of the tee or the flange legs of the angles are additive in compression, e.g., when a tee is used as a bracing member and the connection of this member is made to the flange, a bulge in the interaction curve occurs. As a result, Eqs. 6.9.2.2.1-1 and 6.9.2.2.1-2 may significantly underestimate the resistance in such cases. Alternative approaches attempting to capture this bulge have proven to be generally inconclusive or incomplete. Therefore, it is recommended that Eqs. 6.9.2.2.1-1 and 6.9.2.2.1-2 be conservatively applied to these cases. Should significant additional resistance be required, the use of one or more of these alternative approaches, as described in White (2022), may be considered.

Tee stems and double-angle web legs in which the toe of the stem or leg is in flexural compression are not considered as compact elements; therefore, Eq. 6.9.2.2.1-3 should be applied in cases where the toe of the tee stem or double-angle web legs are subject to flexural compression. Tee stems and double-angle web legs in which the toe of the stem or leg is in flexural tension are considered as compact elements; thus, Eqs. 6.9.2.2.1-1 and 6.9.2.2.1-2 may be applied in this case.

6.9.2.2.2—Interaction with Torsional and/or Flexural Shear

For the following member types:

- noncomposite rectangular box-section members, including square and rectangular HSS, and
- noncomposite circular tubes, including round HSS,

when the member is subjected to torsion resulting in a maximum ratio of the factored torsional shear stress to the corresponding cross-section element factored shear resistance, $f_{vt}/\phi_T F_{cv}$, greater than 0.2, the factored torsional shear stresses shall be considered within the applicable strength interaction equations as specified herein.

For general members, including those specified above, where P_u/P_r is greater than 0.05, the factored flexural shear stresses shall be considered within the applicable strength interaction equations as specified herein; otherwise, the factored flexural shear stresses need not be considered.

Where the consideration of both the torsional and flexural shear stresses is required, the torsional and flexural shear stresses shall be summed based on their corresponding directions in each of the plate elements of the cross-section, given the internal loadings. Where either of the above exclusion conditions are met, the

C6.9.2.2.2

Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3 address the influence of torsional and/or flexural shear, as applicable, on the resistance of noncomposite rectangular box-section members and noncomposite circular tubes, including round HSS. In addition, they address the interaction between the flexural shear resistance and the axial resistance of I-section members. I-section members with thin webs, subjected to significant axial force, potentially have a measurable interaction between their flexural shear and axial load resistances. The interaction between torsional and/or flexural shear stresses in I-section member flanges with other member resistances is neglected in these provisions.

Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3 are based on an interaction between the shear resistance and the combined axial and flexural resistance of the member and its component plates in which the axial and flexural strength ratios are taken as linear terms, with an exponent of 1, and the torsional and/or flexural shear strength ratio is taken as a quadratic term with an exponent of 2. The interaction with the torsional and/or flexural shear is applied to the axial compressive and flexural resistance terms, rather than writing a separate term involving the torsional and/or flexural shear in the strength interaction equations.

corresponding contributions to the shear stresses shall be taken as zero. When the corresponding flexural shear, torsional shear and/or combined shear stress, as applicable is nonzero:

- P_r shall be multiplied by Δ ,
- M_{rx} shall be multiplied by Δ_x , and
- M_{ry} shall be multiplied by Δ_y

in Eqs. 6.9.2.2.1-1 through 6.9.2.2.1-3.

Δ , Δ_x , and Δ_y shall be computed as follows:

$$\Delta = 1 - \left(\frac{f_{ve}}{\phi_T F_{cv}} \right)^2 > 0 \quad (6.9.2.2.2-1)$$

$$\Delta_x = 1 - \left(\frac{f_{vex}}{\phi_T F_{cvx}} \right)^2 > 0 \quad (6.9.2.2.2-2)$$

$$\Delta_y = 1 - \left(\frac{f_{vey}}{\phi_T F_{cyy}} \right)^2 > 0 \quad (6.9.2.2.2-3)$$

where:

ϕ_T = resistance factor for torsion specified in Article 6.5.4.2

f_{ve} = total factored shear stress due to torsion and/or flexure, as applicable, calculated in a cross-section element oriented parallel to the x - or y -axis of the cross-section (ksi)

f_{vex} = total factored shear stress due to torsion and/or flexure, as applicable, calculated in a cross-section element oriented parallel to the x -axis of the cross-section (ksi)

f_{vey} = total factored shear stress due to torsion and/or flexure, as applicable, calculated in a cross-section element oriented parallel to the y -axis of the cross-section (ksi)

F_{cvx} ,
 F_{cyy} = nominal shear resistance of a cross-section element under consideration parallel to the x - and y -axis, respectively, taken as F_{cv} for that element as specified below (ksi)

F_{cv} = for noncomposite rectangular box-section members, including square and rectangular HSS, and for webs of I- and H-section members, the nominal shear buckling resistance of the cross-section element under consideration,

The interaction assumed by Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3 gives an accurate to moderately conservative representation of the plastic strength interaction between normal and shear stresses obtained from the von Mises yield criterion, the inelastic buckling interaction in plates subjected to combined uniform axial compression and shear, and the elastic buckling interaction in plates subjected to combined bending within the plane of the plate and shear (Ziemian, 2010). The theoretical interaction curve between the normalized strength ratios is circular for each of these cases, which would result in the expressions within Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3 being taken to the $1/2$, or square root, power. However, the plate elastic buckling interaction between uniform axial compression and shear is approximated more closely by an interaction equation involving a linear term for the axial compressive strength ratio and a quadratic term for the shear strength ratio, which results in the form given by Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3 (Ziemian, 2010). The largest difference between the overall strengths predicted by the circular interaction and the interaction using a linear term for the axial compressive strength ratio and a quadratic term for the shear strength ratio is 15 percent, corresponding to a shear strength ratio of 0.707. Also, the ultimate shear resistance in the theoretical elastic shear buckling range is larger than the theoretical elastic shear buckling resistance, due to post-buckling action. In these provisions, the interaction based on using a linear term for the axial compressive and flexural strength ratios is adopted to characterize the member for all of the types of loading considered. This is consistent with the form of the interaction equations in AISC (2022b) for torsion combined with axial force and flexure.

Although the interaction between the shear resistance and the axial and flexural resistances for box-section members is based largely on the theoretical strength interactions for the individual component plates, these interaction relationships are conflated into an overall member interaction relationship. This is comparable to the handling of the strength interactions for these types of members in AISC (2022b). Schilling (1965) shows that an interaction equation with the axial and moment strength ratios combined linearly and the shear strength ratio combined as a quadratic term gives a conservative estimate of the overall member resistance for noncomposite circular tube members governed by overall member elastic or inelastic buckling (Ziemian, 2010). Schilling's results provide additional justification for the use of Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3 for these types of members.

flexural resistance, i.e., f_{ve}/F_{cvx} on M_{ry} and f_{vey}/F_{cyy} on M_{rx} , is taken to be negligible.

Figure C6.9.2.2.2-2 shows a comparable illustration to Figure C6.9.2.2.2-1 for a representative circular tube section. In this case, the shears can be added vectorially and the resultant shear can be applied to the cross-section to calculate the maximum contribution to the shear strength ratio from the flexural shears. The shear stresses from torsion are constant throughout the circumference of the tube, assuming constant thickness of the tube, and can be added to the maximum flexural shear stress to obtain the maximum total stress due to combined flexure and torsion. The corresponding f_{ve}/F_{cv} ratio is applied conservatively to P_r , M_{rx} , and M_{ry} . For circular tubes subjected to combined flexural shear and torsion, the shear resistance is taken conservatively as the cross-section torsional shear buckling resistance, written in terms of stress, since this is smaller than the corresponding flexural shear buckling resistance.

Figure C6.9.2.2.2-2—Representative Circular Tube Cross-section Profile Showing Internal Forces and Corresponding Element Stresses

As specified in Article 6.12.1.2.2, circular tube members subject to flexural shear and torsion must be checked using Eq. 6.12.1.2.3a-5 in addition to the interaction of the flexural or torsional shear resistances with the member axial and flexural resistances using the equations within this Article.

Figure C6.9.2.2.2-3 shows an illustration of a representative I- or H-section member, subjected to biaxial bending, M_{ux} and M_{uy} , biaxial shear, V_{ux} and V_{uy} , and torque, T_u . For these member types, the shear stresses due to torsion, and the flange shear stresses due to flexure are generally small and are assumed negligible. However, thin-web I-section members can be subject to significant web shear stresses. These stresses may have a significant influence on the member axial load resistance. For instance, the interaction between axial compression and

web shear may be measurable in edge girders of cable-stayed bridges. Eq. 6.9.2.2.2-1 captures this strength limit state response.

Figure C6.9.2.2.2-3—Representative I- or H-section Profile Showing Internal Forces and Corresponding Plate-Element Stresses

For I-section and H-section member webs and box-section member webs and flanges, the shear resistance is based on the theoretical shear buckling resistances, as represented by Eqs. 6.11.8.2.2b-5, 6.11.8.2.2b-6 and 6.11.8.2.2b-7, using $k_s = 5.34$ for longitudinally unstiffened plates by reference to Article 6.11.8.2.2, and using the shear buckling coefficient from Article 6.11.8.2.3 for longitudinally stiffened plates. White et al. (2019b) provide alternative equations, derived from Eurocode 3 Part 1-5, that quantify the shear buckling resistance for longitudinally stiffened plates in noncomposite box-section members having any number of longitudinal stiffeners, not necessarily equally spaced, which account for the additional lateral restraint from transverse stiffeners when the transverse stiffeners are spaced at less than or equal to three times the plate width. These equations may be employed to realize a larger shear resistance for close transverse stiffener spacing.

In I- and H-section members subjected to torsion, the flanges may be subjected to significant additional lateral bending due to the restraint of warping. This additional flange lateral bending may be considered by calculating M_{uy}/M_{ry} considering each of the individual flanges as a separate component, and then combining the larger of these M_{uy}/M_{ry} values with the other strength ratios in the appropriate strength interaction equations. Alternatively, for I-section members subjected to major- and minor-axis bending plus torsion, the one-third rule provisions of Article 6.10 may be employed to assess these combined effects.

Also, for circular tubes, the shear resistance is taken as the theoretical flexural or torsional shear buckling resistance when considering the force interaction effects in these provisions. The interaction between shear post-buckling and the other member resistances is considered to not be sufficiently established, for general cases, to permit the consideration of interaction of shear post-buckling resistance with the other resistances.

The interaction of flange flexural shear stresses with the axial and flexural resistances of the member is assumed to be negligible for I-section and H-section members designed by these Specifications. The weak-axis shear resistance of these types of members is checked using Article 6.12.1.2.3a.

When the maximum ratio of the factored torsional shear stress to the corresponding cross-section element factored shear resistance, $f_{ve}/\phi T F_{cv}$ is less than 0.2, the reduction in the member and plate axial compressive and flexural resistances due to the torsional shear stress is less than 4 percent, and is therefore neglected. Furthermore, when P_u/P_r is less than or equal to 0.05, the influence of this term on the unity check in Eqs. 6.9.2.2.1-1 through 6.9.2.2.1-3 is always less than or equal to 0.05. As such, the effect of the axial force on the design of the member may be neglected, as indicated in Articles C6.10.6.1 and C6.11.6.2.1.

In addition, when P_u/P_r is less than or equal to 0.05, the influence of flexural shear stresses may be neglected when applying Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3. This recognizes the well-established observation that moment-shear strength interaction is small and may be neglected in I- and box-girder flexural members (White et al., 2008) (Johansson et al., 2007) (AISC, 2022b). When evaluating the factored shear resistance of a member subject to torsion, additive shear stresses from flexure and from torsion are to be considered. However, these additive shear stresses need not be considered in evaluating the strength interaction in Article 6.9.2.2.2 when the exclusion clauses permitting the torsional shear stress and/or the flexural shear stress to be neglected are satisfied.

Flexural shear stresses in flanges need not be considered in Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3. The flange shear stresses due to flexure, which are tangent to the wall of the flange plate, are maximum at the connection to the webs, zero at a location within the middle of the plate, and the net shear force in the flanges is zero. The flexural shear stresses in flange elements of I-section members subjected to major-axis bending also need not be considered in Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3 for similar reasons. That is, flexural shear stresses only need to be considered in the member web or webs.

It should be noted that in box-section members, the flanges associated with one direction of bending are the webs associated with the other direction of bending, and vice versa. Therefore, for members subjected to biaxial bending, the same elements must be designed as a web

element for bending in one direction, and as a flange element for bending in the other direction.

When addressing the additional interaction with torsion and/or flexural shear using the equations specified in Article 6.9.2.2.1, the maximum torsional shear and/or flexural shear ratios, $f_{ve}/\phi TF_{cv}$, $f_{vex}/\phi TF_{cvx}$, and $f_{vey}/\phi TF_{cvy}$, which produce the corresponding minimum Δ , Δ_x and Δ_y values, are to be combined with the other strength ratios determined according to Article 6.9.2.2.1 within each of the smallest unbraced lengths along the overall member length. Based on the above considerations, the f_{ve} , f_{vex} and/or f_{vey} values in Article 6.9.2.2.1 may be taken as the combined torsional and flexural shear stresses, the torsional shear alone, the flexural shear alone, or zero.

In lieu of a refined analysis, the factored torsional shear stresses in the cross-section element under consideration for use in Eqs. 6.9.2.2.2-1 through 6.9.2.2.2-3 may be calculated as follows:

- For noncomposite circular tubes, including round HSS:

$$= \frac{T_u}{2\pi r^2 t} \quad (\text{C6.9.2.2.2-1})$$

- For web and flange elements of noncomposite rectangular box-section members, including square and rectangular HSS:

$$= \frac{T_u}{2A_o t} \quad (\text{C6.9.2.2.2-2})$$

where:

- A_o = enclosed area within the box section (in.²)
- T_u = factored torque (kip-in.)
- r = radius to the mid-thickness of the tube (in.)
- t = element thickness (in.); for HSS, the provisions of Article 6.12.1.2.4 shall apply.

6.9.3—Limiting Slenderness Ratio for Compression Members

For members subject to compression only or for evaluating the compression slenderness of tension members subject to stress reversal, the following slenderness requirements shall apply:

- For primary members:..... $\frac{K\ell}{r} \leq 120$
- For secondary members:..... $\frac{K\ell}{r} \leq 140$

where:

- K = effective length factor, specified in Article 4.6.2.5
- ℓ = unbraced length (in.)

r = minimum radius of gyration (in.)

For evaluating the tension slenderness of compression members subject to stress reversal, the provisions of Article 6.8.4 shall apply.

For the purpose of this Article only, the radius of gyration may be computed on a notional section that neglects part of the area of a component, provided that:

- the capacity of the component based on the actual area and radius of gyration exceeds the factored loads, and
- the capacity of the notional component based on a reduced area and corresponding radius of gyration also exceeds the factored loads.

6.9.4—Noncomposite Members

6.9.4.1—Nominal Compressive Resistance

6.9.4.1.1—General

The nominal compressive resistance, P_n , shall be taken as the smallest value based on the applicable modes of flexural buckling, torsional buckling, and flexural-torsional buckling as follows:

- Applicable buckling modes for doubly symmetric members:
 - Flexural buckling
 - Torsional buckling for open-section members in which the effective torsional unbraced length is larger than the effective lateral unbraced length
- Applicable buckling modes for singly symmetric members:
 - Flexural buckling
 - Flexural-torsional buckling for open-section members
- Applicable buckling modes for unsymmetric members:
 - Flexural-torsional buckling for open-section members, except that single-angle members shall be designed according to the provisions of Article 6.9.4.4 using the flexural buckling resistance equations with an effective slenderness ratio of $(K\ell/r)_{eff}$
- Applicable buckling modes for closed-section members:
 - Flexural buckling

C6.9.4.1.1

Eqs. 6.9.4.1.1-1 and 6.9.4.1.1-2 are equivalent to the corresponding axial compressive resistance equations given in AISC (2022b). These baseline equations are applicable for cross-sections without any longitudinal stiffeners and in which all the component elements satisfy the corresponding width-to-thickness or slenderness ratio limits specified in Article 6.9.4.2.1. The equations are written in terms of the elastic critical buckling resistance, P_e , and the nominal yield resistance, P_o , to facilitate the calculation of the nominal resistance for members subject to buckling modes in addition to, or other than, flexural buckling. Also, this form of the resistance equations may be used to conveniently calculate P_n when a refined buckling analysis is employed to assess the stability of trusses, frames or arches in lieu of utilizing an effective length factor approach (White, 2022). In such cases, P_e in Eqs. 6.9.4.1.1-1 and 6.9.4.1.1-2 would be taken as the axial load in a given member taken from the analysis at incipient elastic buckling of the structure or subassembly.

Eqs. 6.9.4.1.1-1 and 6.9.4.1.1-2 are approximately the same as column strength curve 2P of Ziemian (2010). These equations are based on a mean out-of-straightness of $L/1500$. The development of the mathematical form of these equations is described in Tide (1985), and the structural reliability they are intended to provide in the context of building design applications is discussed in Galambos (2006). Due to the large torsional stiffness of closed-section members, the reduction in the resistance due to the influence of torsional buckling deformations is small. Therefore, only flexural buckling is considered for closed-section members.

For compression members with cross-sections containing any slender elements, i.e., cross-sections containing one or more longitudinal unstiffened elements not satisfying the corresponding width-to-thickness or

For compression members with cross-sections composed only of nonslender longitudinally unstiffened elements satisfying the width-to-thickness or slenderness ratio limits specified in Article 6.9.4.2.1, P_n shall be determined as follows:

- If $\frac{P_o}{P_e} \leq 2.25$, then:

$$P_n = \left[0.658 \left(\frac{P_o}{P_e} \right) \right] P_o \quad (6.9.4.1.1-1)$$

- Otherwise:

$$P_n = 0.877 P_e \quad (6.9.4.1.1-2)$$

where:

- A_g = gross cross-sectional area of the member (in.²)
 F_y = specified minimum yield strength; for nonhomogeneous cross-section members, F_y may be taken as the smallest specified minimum yield strength of all the cross-section elements in lieu of a more refined calculation (ksi)
 P_e = elastic critical buckling resistance determined as specified in Article 6.9.4.1.2 for flexural buckling, and as specified in Article 6.9.4.1.3 for torsional buckling or flexural-torsional buckling, as applicable (kip)
 P_o = nominal yield resistance = $F_y A_g$ (kip)

Table 6.9.4.1.1-1 may be used for guidance in selecting the appropriate potential column-buckling mode(s) to be considered in the determination of P_n , and the equations to use for the calculation of P_e .

For compression members with cross-sections containing any slender elements, P_n shall be determined as specified in Article 6.9.4.2.2. For compression members with cross-sections containing any longitudinally stiffened plates, P_n shall be determined as specified in Article E6.1.

slenderness ratio limits specified in Article 6.9.4.2.1, P_n is instead to be determined according to the provisions of Article 6.9.4.2.2 to account for the effect of potential local buckling of those elements on the overall buckling resistance of the member. For longitudinally stiffened plates, the effects of the longitudinal stiffeners and their tributary plate width acting as stiffener struts, as well as the potential local buckling of the individual stiffened plate panels, are addressed directly in Article E6.1.3.

For nonhomogeneous cross-section members, this Article specifies conservatively that F_y may be taken as the smallest specified minimum yield strength of all the cross-section elements for the calculation of P_o . White et al. (2019b) discuss a more rigorous approach for the calculation of P_o for nonhomogeneous members with doubly symmetric I- and box-section profiles.

For bearing stiffeners, only the limit state of flexural buckling is applicable. In addition, given the width-to-thickness ratio limits for bearing stiffener cross-section elements specified by Articles 6.10.11.2.2 and 6.10.11.2.4b, bearing stiffeners are effectively composed only of nonslender elements. The contribution of a thin web to the bearing stiffener axial compressive resistance is accounted for within the effective section provisions of Article 6.10.11.2.4b. As such, Article 6.9.4.1.1 is applicable for calculating the axial compressive resistance of bearing stiffeners.

The need for consideration of local buckling of slender plate elements via Article 6.9.4.2.2, and the need for consideration of longitudinal stiffeners and their tributary plate width acting as stiffener struts as well as the potential local buckling of the individual stiffened plate panels via Article E6.1, is avoided by using longitudinally unstiffened plates satisfying the requirement of Eq. 6.9.4.2.1-1. This equation references the nonslender longitudinally unstiffened plate limits specified in Table 6.9.4.2.1-1.

In some cases, it may be more economical to use members having one or more slender plates in which the strength is reduced due to local buckling effects. For instance, rolled wide-flange sections with ratios of $d/b_f \geq 1.7$, where d is the section depth and b_f is the flange width, typically have slender webs for uniform axial compression. Webs of welded I- and box sections also typically are classified as slender elements for axial compression according to Eq. 6.9.4.2.1-1. Flanges of welded box-section members subject to bending and axial compression may be slender with respect to the axial compressive resistance in regions of low bending

moment, since less plate thickness is needed to resist the axial force plus bending in these regions for a given plate width. The stems of a significant number of rolled T-sections and one or both legs of many rolled angle sections are also classified as slender elements. Furthermore, a large number of square or rectangular HSS profiles have slender wall elements corresponding to a member subjected to axial compression.

Article CE6.1.3 discusses cases where it may or may not be beneficial to consider longitudinal stiffening of cross-section plate elements.

Flowcharts illustrating the application of the provisions of Article 6.9.4 for determining the compressive resistance of noncomposite I- or box-section members, with or without longitudinally stiffened plates, are provided in Article C6.5.1 in Appendix C6.

Table 6.9.4.1.1-1—Selection Table for Determination of Nominal Compressive Resistance, P_n

Cross-section	Potential Column-Buckling Mode	Applicable Equation for P_e
	FB	(6.9.4.1.2-1)
	and if $K_z \ell_z > K_y \ell_y$: TB	(6.9.4.1.3-1) Note: see also Article C6.9.4.1.3
	FB	(6.9.4.1.2-1)
	and: FTB	(6.9.4.1.3-2) Note: see also Article C6.9.4.1.3
	FB	(6.9.4.1.2-1) Note: for built-up sections, see also Article 6.9.4.3
	FB	(6.9.4.1.2-1)
	FB	(6.9.4.1.2-1)
	and: FTB	(6.9.4.1.3-2) Note: see also Article C6.9.4.1.3
	FB	(6.9.4.1.2-1) Note: see also Articles 6.9.4.4 and C6.9.4.4
	FB	(6.9.4.1.2-1) Note: see also Article 6.9.4.3
	and: FTB	(6.9.4.1.3-2) Note: see also Article C6.9.4.1.3
	FB	(6.9.4.1.2-1)
Unsymmetric Open Sections	FTB	(6.9.4.1.3-7) Note: see also Article C6.9.4.1.3
Unsymmetric Closed Sections	FB	(6.9.4.1.2-1)
Bearing Stiffeners	FB	(6.9.4.1.2-1) Note: See also Article 6.10.11.2.4

where:
 FB = flexural buckling
 TB = torsional buckling
 FTB = flexural-torsional buckling

Note: For compression members with cross-sections containing any slender elements, P_n is to be determined according to the provisions of Article 6.9.4.2.2 to account for the effect of potential local buckling of those cross-section elements on the overall compressive resistance of the member. For compression members with cross-sections containing any longitudinally stiffened plates, P_n is to be determined according to the provisions of Article E6.1.1 to account for the action of the longitudinal stiffeners and their tributary plate widths acting as stiffener struts including any local buckling effects in slender longitudinally stiffened plate panels. In such cases, the same potential column-buckling modes and corresponding values of P_e given in this table shall be considered in the computation of P_n .

6.9.4.1.2—Elastic Flexural Buckling Resistance

In lieu of an alternative buckling analysis, the elastic critical buckling resistance, P_e , based on flexural buckling shall be taken as:

$$P_e = \frac{\pi^2 E}{\left(\frac{K\ell}{r_s}\right)^2} A_g \quad (6.9.4.1.2-1)$$

where:

- E = modulus of elasticity of steel (ksi)
- A_g = gross cross-sectional area of the member (in.²)
- K = effective length factor in the plane of buckling determined as specified in Article 4.6.2.5
- ℓ = unbraced length in the plane of buckling (in.)
- r_s = radius of gyration about the axis normal to the plane of buckling (in.)

6.9.4.1.3—Elastic Torsional Buckling and Flexural–Torsional Buckling Resistance

In lieu of an alternative buckling analysis, for open-section doubly symmetric members, the elastic critical buckling resistance, P_e , based on torsional buckling shall be taken as:

$$P_e = \left[\frac{\pi^2 EC_w}{(K_z \ell_z)^2} + GJ \right] \frac{A_g}{I_x + I_y} \quad (6.9.4.1.3-1)$$

where:

- A_g = gross cross-sectional area of the member (in.²)
- C_w = warping torsional constant (in.⁶)
- G = shear modulus of elasticity for steel = 0.385E (ksi)
- I_x, I_y = moments of inertia about the major and minor principal axes of the cross-section, respectively (in.⁴)
- J = St. Venant torsional constant (in.⁴)
- $K_z \ell_z$ = effective length for torsional buckling (in.)

In lieu of an alternative buckling analysis, for open-section singly symmetric members where y is the axis of symmetry of the cross-section, the elastic critical buckling resistance, P_e , based on flexural–torsional buckling shall be taken as:

$$P_e = \left(\frac{P_{ey} + P_{ez}}{2H} \right) \left[1 - \sqrt{1 - \frac{4P_{ey}P_{ez}H}{(P_{ey} + P_{ez})^2}} \right] \quad (6.9.4.1.3-2)$$

in which:

C6.9.4.1.2

Flexural buckling of concentrically loaded compression members refers to a buckling mode in which the member deflects laterally without twist or a change in the cross-sectional shape. Flexural buckling involves lateral displacements of the member cross-sections in the direction perpendicular to the x - or y -axes that are resisted by the flexural rigidities, EI_x or EI_y , of the member, respectively.

Eq. 6.9.4.1.2-1 should be used to calculate the critical flexural buckling resistances about the x - and y -axes, with the smaller value taken as P_e for use in Eq. 6.9.4.1.1-1 or 6.9.4.1.1-2, as applicable.

C6.9.4.1.3

Torsional buckling of concentrically loaded compression members refers to a buckling mode in which the member twists about its shear center. Torsional buckling applies only for open-section doubly symmetric compression members for which the locations of the centroid and shear center coincide. Torsional buckling will rarely control and need not be considered for doubly symmetric I-section members satisfying the cross-section proportion limits specified in Article 6.10.2, unless the effective length for torsional buckling is significantly larger than the effective length for y -axis flexural buckling. The effective length for torsional buckling, $K_z \ell_z$, is typically taken as the length between locations where the member is prevented from twisting. That is, in many cases, $K_z \ell_z$ can be taken conservatively as $1.0\ell_z$. For a cantilever member fully restrained against twisting and warping at one end with the other end free, $K_z \ell_z$ should be taken as 2ℓ where ℓ is the length of the member (White, 2022). For a member with twisting and warping restrained at both ends, $K_z \ell_z$ may be taken as 0.5ℓ . For a doubly symmetric I-section, C_w may be taken as $I_y h^2/4$, where h is the distance between flange centroids, in lieu of a more precise analysis. For closed sections, C_w may be taken equal to zero and GJ is relatively large. Because of the large GJ , torsional buckling and flexural–torsional buckling need not be considered for closed sections, including built-up members connected by lacing bars, batten plates, perforated plates, or any combination thereof.

Flexural–torsional buckling of concentrically loaded compression members refers to a buckling mode in which the member twists and bends simultaneously without a change in the cross-sectional

$$H = 1 - \frac{y_o^2}{\bar{r}_o^2} \quad (6.9.4.1.3-3)$$

$$P_{ey} = \frac{\pi^2 E}{\left(\frac{K_y \ell_y}{r_y} \right)^2} A_g \quad (6.9.4.1.3-4)$$

$$P_{ez} = \left(\frac{\pi^2 E C_w}{(K_z \ell_z)^2} + GJ \right) \frac{1}{\bar{r}_o^2} \quad (6.9.4.1.3-5)$$

$$\bar{r}_o^2 = y_o^2 + \frac{I_x + I_y}{A_g} \quad (6.9.4.1.3-6)$$

where:

- $K_y \ell_y$ = effective length for flexural buckling about the y-axis (in.)
 $\bar{r}_o$ = polar radius of gyration about the shear center (in.)
 r_y = radius of gyration about the y-axis (in.)
 y_o = distance along the y-axis between the shear center and centroid of the cross-section (in.)

In lieu of an alternative buckling analysis, for open-section unsymmetric members, the elastic critical buckling resistance, P_e , based on flexural-torsional buckling shall be taken as the lowest root of the following cubic equation:

$$\begin{aligned} (P_e - P_{ex})(P_e - P_{ey})(P_e - P_{ez}) - P_e^2 (P_e - P_{ey}) \left(\frac{x_o}{r_o} \right)^2 \\ - P_e^2 (P_e - P_{ex}) \left(\frac{y_o}{r_o} \right)^2 = 0 \end{aligned} \quad (6.9.4.1.3-7)$$

in which:

$$P_{ex} = \frac{\pi^2 E}{\left(\frac{K_x \ell_x}{r_x} \right)^2} A_g \quad (6.9.4.1.3-8)$$

$$\bar{r}_o^2 = x_o^2 + y_o^2 + \frac{I_x + I_y}{A_g} \quad (6.9.4.1.3-9)$$

where:

- $K_x \ell_x$ = effective length for flexural buckling about the x-axis (in.)
 r_x = radius of gyration about the x-axis (in.)

shape. Compression members composed of open singly symmetric cross-sections, where the y-axis is defined as the axis of symmetry of the cross-section, can fail either by flexural buckling about the x-axis or by torsion combined with flexure about the y-axis. Compression members composed of open unsymmetric cross-sections, or members with no cross-section axis of symmetry, fail by torsion combined with flexure about the x- and y-axes. In both of the preceding cases, the centroid and shear center of the cross-section do not coincide. As buckling occurs, the axial stresses have a lateral component resulting from the lateral deflection of the member. This lateral component, acting about the shear center of the cross-section, causes simultaneous twisting of the member. The degree of interaction between the torsional and flexural deformations determines the reduction of this buckling load in comparison to the flexural buckling load (Ziemian, 2010). As the distance between the centroid and shear center increases, the twisting tendency increases and the flexural-torsional buckling load decreases. Flexural-torsional buckling may be a critical mode of failure for thin-walled open-section singly symmetric compression members, e.g., tees, double angles, and channels, and for open-section unsymmetric compression members due to their relatively low torsional rigidity. For open-section singly symmetric members, the critical flexural-torsional buckling resistance is always smaller than the critical flexural buckling resistance about the y-axis, P_{ey} . Therefore, in such cases, only flexural buckling about the x-axis need be considered along with flexural-torsional buckling. For open-section unsymmetric members, only flexural-torsional buckling is applicable; flexural buckling about the x- and y-axes need not be checked except that single-angle members are to be designed according to the provisions of Article 6.9.4.4 using only the flexural buckling resistance equations with an effective slenderness ratio $(K\ell/r)_{eff}$ (AISC, 2022b).

Eqs. 6.9.4.1.3-2 through 6.9.4.1.3-6 assume that the y-axis is defined as the axis of symmetry of the cross-section. Therefore, for a channel, the y-axis should actually be taken as the x-axis of the cross-section, or the axis of symmetry for the channel section, when applying these equations. C_w should conservatively be taken equal to zero for tees and double angles in the application of these equations. Refer to Article C6.12.2.2.4 for additional information on the calculation of the St. Venant torsional constant J for tees and double angles. For channels, refer to Article C6.12.2.2.5 for additional information on the calculation of C_w and J .

For singly symmetric I-section compression members with equal flange widths and differing flange thicknesses, flexural-torsional buckling need not be considered as long as $0.67 \leq t_{f1}/t_{f2} \leq 1.5$ and $K_z \ell_z \leq K_y \ell_y$, where t_{f1} and t_{f2} are the flange thicknesses and K_z and K_y are the effective length factors for torsional

x_o = distance along the x -axis between the shear center and centroid of the cross-section (in.)

buckling and for flexural buckling about the y -axis, respectively (White, 2022). However, flexural-torsional buckling should always be checked for singly symmetric I-sections that are loaded in axial compression when the flange widths are different. C_w may be computed as follows for such sections in lieu of a more precise analysis (Salmon et al., 2009):

$$C_w = \frac{t_f h^2}{12} \left(\frac{b_1^3 b_2^3}{b_1^3 + b_2^3} \right) \quad (\text{C6.9.4.1.3-1})$$

where:

b_1, b_2 = individual flange widths (in.)
 h = distance between flange centroids (in.)
 t_f = flange thickness (in.); use an average thickness if the flange thicknesses differ.

6.9.4.2—Effects of Local Buckling on the Nominal Compressive Resistance

6.9.4.2.1—Classification of Cross-Section Elements

Longitudinally unstiffened cross-section elements satisfying the following limit shall be defined as nonslender under member axial compression:

$$\frac{b}{t} \leq \lambda_r \quad (6.9.4.2.1-1)$$

where:

λ_r = corresponding width-to-thickness or slenderness ratio limit as specified in Table 6.9.4.2.1-1
 b = element width as specified in Table 6.9.4.2.1-1 (in.)
 t = element thickness (in.); for flanges of rolled channels, use the average thickness; for HSS, the provisions of Article 6.12.1.2.4 shall apply.

Local buckling effects shall be neglected for nonslender longitudinally unstiffened cross-section elements. Otherwise, longitudinally unstiffened elements shall be defined as slender under member axial compression and local buckling effects shall be considered according to the provisions of Article 6.9.4.2.2. For longitudinally stiffened cross-section elements, the strength of the stiffener struts, including potential local buckling effects, shall be considered according to the provisions of Article E6.1.

C6.9.4.2.1

Compression members with cross-sections composed only of nonslender longitudinally unstiffened elements, i.e., cross-sections without any longitudinal stiffeners in which all the component elements satisfy the corresponding width-to-thickness or slenderness ratio limits specified herein, are able to develop their full yield strength under uniform axial compression without any significant impact from local buckling. For compression members with cross-sections containing any slender elements, i.e., longitudinally unstiffened elements not satisfying the corresponding width-to-thickness or slenderness ratio limits specified herein, the nominal compressive resistance is instead to be determined according to the provisions of Article 6.9.4.2.2 to account for the effect of potential local buckling of those cross-section elements on the overall compressive resistance of the member. White et al. (2019b) provide a detailed discussion of the background to these limits. For longitudinally stiffened plates, the effects of local buckling of the individual panels are addressed in Article E6.1.3.

Table 6.9.4.2.1-1—Element Width-to-Thickness or Slenderness Ratio Limits and Element Widths for Axial Compression

Elements Supported Along One Longitudinal Edge	λ_r	b
Stems of Rolled Tees	$0.75 \sqrt{\frac{E}{F_y}}$	Full depth of tee
Flanges of Rolled I-, Tee, and Channel Sections; Plates Projecting from Rolled I-Sections; and Outstanding Legs of Double Angles in Continuous Contact	$0.56 \sqrt{\frac{E}{F_y}}$	- Half-flange width for rolled I- and T-sections - Full-flange width for channel sections - Distance between free edge and first line of bolts or welds for plates projecting from rolled I-sections - Full width of an outstanding leg for double angles in continuous contact
Flanges of Welded and Nonwelded Built-Up I-Sections; and Plates or Angle Legs Projecting from Built-Up I-Sections	$0.64 \sqrt{\frac{k_c E}{F_y}}$	Half-flange width for welded and nonwelded built-up I-sections
Outstanding Legs of Single Angles; Outstanding Legs of Double Angles with Separators; Flange Extensions of Box Sections; Plates or Angle Legs Projecting from Welded and Nonwelded Built-Up I- or Box Sections; and All Other Plates Supported along One Longitudinal Edge	$0.45 \sqrt{\frac{E}{F_y}}$	- Full width of outstanding leg for single angle or double angles with separators - Full projecting width for all others
Elements Supported along Two Longitudinal Edges	λ_r	b
Perforated Cover Plates	$1.86 \sqrt{\frac{E}{F_y}}$	Clear distance between edge supports; see also the paragraph at the end of Article 6.9.4.3.2
Webs of Rolled I- and Channel Sections; Webs of Nonwelded Built-Up I- and Channel Sections	$1.49 \sqrt{\frac{E}{F_y}}$	- Clear distance between flanges minus the fillet or corner radius at each flange for webs of rolled I- and channel sections - Distance between adjacent lines of bolts for webs of nonwelded built-up I- and channel sections
Flanges and Webs of Nonwelded Built-Up Box Sections; Walls of Square and Rectangular Hot-Formed HSS; and Nonperforated Flange Cover Plates	$1.40 \sqrt{\frac{E}{F_y}}$	- Distance between adjacent lines of bolts for flanges of nonwelded built-up box sections - Distance between adjacent lines of bolts for webs of nonwelded built-up box sections - Clear distance between walls minus inside corner radius on each side for HSS. Use the outside dimension minus three times the appropriate design wall thickness for HSS, specified in Article 6.12.1.2.4 if the corner radius is not known. - Distance between lines of welds or bolts for nonperforated flange cover plates

(continued on next page)

Elements Supported Along Two Longitudinal Edges	λ_r	b
Walls of Square and Rectangular Cold-Formed HSS	$1.28 \sqrt{\frac{E}{F_y}}$	Clear distance between walls minus inside corner radius on each side. Use the outside dimension minus three times the appropriate design wall thickness for HSS, specified in Article 6.12.1.2.4 if the corner radius is not known.
All Other Plates Supported along Two Longitudinal Edges	$1.09 \sqrt{\frac{E}{F_y}}$	- Clear distance between flanges for webs of welded I, channel, and box sections - Clear distance between webs for flanges of welded box sections - For angle or T-section stiffener legs or stems connected to a stiffened plate, clear distance between the stiffened plate and the inside of the angle leg or T-section flange not connected to the stiffened plate - Clear distance between edge supports for all others
Other Elements	λ_r	b
Circular Tubes and Round HSS	$0.11 \frac{E}{F_y}$	Outside diameter of the tube
in which: k_c = FLB coefficient, taken as follows: For flanges of welded and nonwelded built-up I-sections: $k_c = \frac{4}{\sqrt{\frac{D}{t_w}}} \quad (6.9.4.2.1-2)$ and $0.35 \leq k_c \leq 0.76 \quad (6.9.4.2.1-3)$ where: D = web depth (in.) t_w = web thickness (in.)		

6.9.4.2.2—Slender Longitudinally Unstiffened Cross-Section Elements

6.9.4.2.2a—General

Compression member cross sections containing one or more longitudinally unstiffened elements not satisfying the corresponding width-to-thickness or slenderness ratio limits specified in Article 6.9.4.2.1, i.e., slender elements, shall be subject to the requirements specified herein.

C6.9.4.2.2a

For compression members containing any slender longitudinally unstiffened cross-section elements local buckling of the component elements may adversely affect the overall buckling resistance of the member. Hence, the nominal compressive resistance, P_n , based on flexural, torsional, or flexural-torsional buckling, as applicable, may be reduced. For such members, P_n is determined

For compression member cross-sections containing any slender elements, the nominal compressive resistance, P_n , shall be taken as the smallest value based on the applicable modes of flexural buckling, torsional buckling, and flexural-torsional buckling, and shall be computed as follows:

$$P_n = F_{cr} A_{eff} \quad (6.9.4.2.2a-1)$$

in which:

$$F_{cr} = \frac{P_{cr}}{A_g} \quad (6.9.4.2.2a-2)$$

A_{eff} = effective area of the cross-section (in.²) determined as specified in Article 6.9.4.2.2c for circular tubes and round HSS. Otherwise, A_{eff} shall be taken as the summation of the effective areas of the cross-section elements determined as follows:

- For rolled-section and hollow structural section members containing slender elements:

$$= A_g - \sum (b - b_e) t \quad (6.9.4.2.2a-3)$$

- Otherwise:

$$= \sum_{lusp} b_e t + \sum_c A_c \quad (6.9.4.2.2a-4)$$

where:

- $\sum_{lusp}$ = summation over all longitudinally unstiffened cross-section plate elements
- $\sum_c$ = summation over all the corner areas of a noncomposite box-section member
- A_c = gross cross-sectional area of the corner pieces of a noncomposite box-section member (in.²)
- A_g = total gross cross-sectional area of the member (in.²)
- b = width of the element under consideration, determined as specified in Table 6.9.4.2.1-1 (in.)
- b_e = effective width of the element under consideration, determined as specified in Article 6.9.4.2.2b for slender elements, and taken equal to b for nonslender elements (in.)
- P_{cr} = nominal compressive resistance of the member calculated from Eq. 6.9.4.1.1-1 or 6.9.4.1.1-2, as applicable, using A_g (kip)
- t = thickness of the element under consideration (in.); for flanges of rolled channels, use the average thickness; for HSS, the provisions of Article 6.12.1.2.4 shall apply.

using a generalized form of the unified effective width/unified effective area approach (AISC, 2022b) (AISI, 2016). Previous specifications utilized a dual philosophy for longitudinally unstiffened plates, commonly referred to as the Q factor method, in which slender elements supported on only one longitudinal edge were assumed to reach their limit of resistance when they attained their theoretical local buckling stress, while slender elements supported on both longitudinal edges utilized an effective width concept to obtain their post-buckling resistance. The unified effective width/unified effective area approach considers the effective width of both of these types of cross-section plate elements. This simplifies the resulting calculations and tends to provide a more accurate characterization of the ultimate strength of all types of slender longitudinally unstiffened plates that recognizes plate post-buckling resistance in all cases. The development and basis of the unified approach is discussed in more detail in the Commentary to Section E7 of AISC (2022b) and in Ziemian (2010).

Two equations are provided for the cross-section effective area to be used in the unified effective width/unified effective area approach. Eq. 6.9.4.2.2a-3 facilitates the inclusion of the fillet areas in rolled-section and square or rectangular hollow structural section members containing any slender elements. Eq. 6.9.4.2.2a-4 addresses general welded and nonwelded built-up sections containing any slender plate elements. The second term of Eq. 6.9.4.2.2a-4 represents the sum of the gross cross-sectional areas of the four corner pieces of a noncomposite box-section member not included in the clear width of the component plates; for all other members, A_c is taken as zero. Flange extensions on box-section members, if present, should be evaluated to determine if they are nonslender or slender elements and included accordingly in Eq. 6.9.4.2.2a-4.

Eqs. 6.9.4.2.2a-1 through 6.9.4.2.2a-4 capture the influence of buckling of individual longitudinally unstiffened plates on the overall member axial compressive resistance in a simple yet accurate to conservative manner. White et al. (2019b) compare this approach to related procedures in AISI (2016) and CEN (2006) and to the results from tests and test simulations.

The original development of the unified effective width/unified effective area method (Peköz, 1986) showed that accurate predictions were obtained for general singly symmetric and unsymmetric beam-columns, with the exception of slender angle sections, when the moment of the axial loads is taken about the centroidal axis of the effective section determined considering axial load alone. AISI (2016) relaxes the requirement that the bending moment should be defined with respect to the centroidal axis of the effective section. The increased eccentricity due to local buckling can have a measurable impact on the resistance of an ideally pinned member; however, this effect tends to become minor in continuous members or members with ends restrained, where the rotations due to these eccentricities are restrained. AISC (2022b) also neglects these effects.

For all cross-section plate elements supported along two longitudinal edges that are slender as specified in this Article, the provisions of Article 6.9.4.5 also shall be satisfied.

6.9.4.2.2b—Effective Width of Slender Elements

The effective width, b_e , of slender elements shall be determined as follows:

- If $\frac{b}{t} \leq \lambda_r \sqrt{\frac{F_y}{F_{cr}}}$, then:

$$b_e = b \quad (6.9.4.2.2b-1)$$

- If $\frac{b}{t} > \lambda_r \sqrt{\frac{F_y}{F_{cr}}}$, then:

$$b_e = b \left[\left(1 - c_1 \sqrt{\frac{F_{el}}{F_{cr}}} \right) \sqrt{\frac{F_{el}}{F_{cr}}} - c_3 \right] \quad (6.9.4.2.2b-2)$$

in which:

c_1 = effective width imperfection adjustment factor determined from Table 6.9.4.2.2b-1

c_2 = effective width imperfection adjustment factor determined from Table 6.9.4.2.2b-1

$$= \left(1 - \sqrt{1 - 4c_1(1 + c_3)} \right) / (2c_1) \quad (6.9.4.2.2b-3)$$

c_3 = effective width imperfection adjustment factor determined from Table 6.9.4.2.2b-1

F_{el} = elastic local buckling stress (ksi)

$$= \left(c_2 \frac{\lambda_r}{(b/t)} \right)^2 F_y \quad (6.9.4.2.2b-4)$$

where:

λ_r = corresponding width-to-thickness ratio limit as specified in Table 6.9.4.2.1-1

b = element width as specified in Table 6.9.4.2.1-1 (in.)

F_{cr} = nominal compressive resistance of the member calculated from Eq. 6.9.4.2.2a-2 (ksi)

t = element thickness (in.); for flanges of rolled channels, use the average thickness; for HSS, the provisions of Article 6.12.1.2.4 shall apply.

For nonhomogeneous members, F_y may be taken as the smallest specified yield strength of all the cross-section elements for the calculation of F_{cr} . White et al. (2019b) discuss a more rigorous approach for the calculation of an effective F_y for the determination of F_{cr} for nonhomogeneous members with doubly symmetric I- and box-section profiles.

C6.9.4.2.2b

Compression member cross-section elements are defined as slender when full yielding of the gross cross-section cannot be developed prior to local buckling impacting the resistance. However, if the stress level at overall member buckling, F_{cr} , is small enough relative to F_y , a slender cross-section element will not exhibit any significant local buckling effects prior to the member reaching its axial compressive resistance. This behavioral attribute is accounted for by checking the element width-to-thickness ratio, b/t , versus the modified limit $\lambda_r \sqrt{F_y/F_{cr}}$. If b/t is smaller than $\lambda_r \sqrt{F_y/F_{cr}}$, no significant local buckling effects occur prior to the member reaching its axial compressive resistance. In these cases, the effective width of the slender cross-section element is equal to the full element width as specified by Eq. 6.9.4.2.2b-1.

Eq. 6.9.4.2.2b-2 is a generalized form of the classical equation for plate local buckling effective widths implemented originally in the AISI (1986) cold-formed steel specifications and developed in the seminal work by Winter (1970). For a plate with ideal simply supported edge conditions, where the theoretical plate local buckling coefficient $k_c = 4.0$, the coefficients in Winter's equation for the plate effective width are $c_1 = 0.22$, $c_2 = 1.485$, and $c_3 = 0.0$. The coefficient $c_3 = 0.075$ for all other plates supported along two longitudinal edges that were not previously mentioned in Table 6.9.4.2.2b-1 shifts Winter's classical plate effective width curve to reflect the results of a wide range of research studies indicating lower local buckling resistances and post-buckling strengths in members composed of general welded plate assemblies, due to the influence of welding residual stresses (White and Lokhande, 2017).

Figure C6.9.4.2.2b-1 shows the compressive resistance, expressed in terms of an average stress on the gross area of the plate, F_n , relative to the minimum specified yield strength F_y , for a welded plate with F_y equal to 50 ksi supported along its two longitudinal edges, for the case where F_{cr} is taken equal to F_y in Eqs. 6.9.4.2.2b-1 and 6.9.4.2.2b-2. One can observe that these types of plates can develop approximately 80 percent of F_y when $b/t = 40$, 60 percent of F_y when $b/t = 60$, and 40 percent of F_y when $b/t = 90$. Traditional AASHTO guidance (AASHTO, 2002) suggested that the b/t of box girder compression flanges should not exceed 60, except in areas of low stress near points of dead load

contraflexure. Figure C6.9.4.2.2b-1 provides more general guidance for preliminary design selection of longitudinally unstiffened plates. Given the magnitude of force that needs to be developed by a plate of a given width, and the yield strength of the plate, the strength curve in this figure can be employed to estimate the required plate thickness. Similar strength curves can be developed for other types of plates and longitudinal edge conditions.

Figure C6.9.4.2.2b-1—Average Stress on the Gross Area of a Welded Plate ($F_y = 50$ ksi) Supported along Two Longitudinal Edges Relative to the Minimum Specified Yield Stress at the Ultimate Strength Condition, F_n/F_y , and for Theoretical Elastic Plate-Buckling, F_{el}/F_y

When calculating the contribution of longitudinally unstiffened plates to the axial compressive resistance of noncomposite steel members, Eqs. 6.9.4.2.2b-1 and 6.9.4.2.2b-2 allow for an increased effectiveness of the plates in longer members where F_{cr} is reduced significantly relative to F_y . This is accomplished by using the unified effective width/unified effective area approach discussed in Article C6.9.4.2.2a.

When calculating the contribution of longitudinally unstiffened compression flange plates in noncomposite steel box-section flexural members, F_{cr} is taken equal to the specified minimum yield strength of the compression flange, F_{yc} , in Eqs. 6.9.4.2.2b-1 and 6.9.4.2.2b-2 based on the provisions of Article 6.12.2.2c. Also, when calculating the contribution of panels in longitudinally stiffened plates to a noncomposite member resistance in axial compression and/or flexure, F_{cr} in Eqs. 6.9.4.2.2b-1 and 6.9.4.2.2b-2 is taken equal to the specified minimum yield strength of the stiffened plate, F_{ysp} , based on the provisions of Article E6.1.3. The member resistance in these cases is best represented by considering the development of F_y on the effective area of the longitudinally unstiffened plates, and/or longitudinally stiffened plate panels.

Table 6.9.4.2.2b-1—Effective Width Imperfection Adjustment Factors, c_1 , c_2 , and c_3

Slender Element	c_1	c_2	c_3
All Plates Supported along One Longitudinal Edge	0.22	1.49	0.0
Perforated Cover Plates	0.22	1.49	0.0
Webs of Rolled I- and Channel Sections; Webs of Nonwelded Built-Up I- and Channel Sections; Webs of Welded and Nonwelded Built-Up I-Sections Containing Two or More Longitudinal Stiffeners; and Flanges and Webs of Welded and Nonwelded Built-Up Box Sections Containing Two or More Longitudinal Stiffeners	0.18	1.31	0.0
Flanges and Webs of Nonwelded Built-Up Box Sections; Walls of Square and Rectangular Hot-Formed HSS; and Nonperforated Flange Cover Plates	0.20	1.38	0.0
Walls of Square and Rectangular Cold-Formed HSS	0.22	1.49	0.0
All Other Plates Supported along Two Longitudinal Edges	0.22	1.74	0.075

6.9.4.2.2c—Effective Area of Circular Tubes and Round HSS

C6.9.4.2.2c

The effective area, A_{eff} , of circular tubes and round HSS shall be determined as follows:

- If $\frac{D}{t} \leq 0.11 \frac{E}{F_y}$, then:

$$A_{eff} = A_g \quad (6.9.4.2.2c-1)$$

- If $0.11 \frac{E}{F_y} < \frac{D}{t} \leq 0.45 \frac{E}{F_y}$, then:

$$A_{eff} = \left(\frac{0.038E}{F_y(D/t)} + \frac{2}{3} \right) A_g \quad (6.9.4.2.2c-2)$$

where:

- A_g = gross cross-sectional area of the tube (in.²)
- D = outside diameter of the tube (in.)
- t = wall thickness of the tube (in.). For round HSS, the provisions of Article 6.12.1.2.4 shall apply.

6.9.4.3—Built-Up Members

6.9.4.3.1—General

C6.9.4.3.1

The provisions of Article 6.9.4.2 shall apply. For built-up members composed of two or more shapes, the slenderness ratio of each component shape between connecting fasteners or welds shall not be more than 75 percent of the governing slenderness ratio of the built-

An effective area is used for circular tubes and round HSS to account for the interaction between local and column buckling. The effective area is determined based on the ratio between the local buckling stress and the yield stress. The local buckling stress is taken from the AISI (2016) provisions based on inelastic action (Winter, 1970) and is based on tests conducted on fabricated and manufactured cylinders. Subsequent tests on fabricated cylinders confirm that Eq. 6.9.4.2.2c-2 is conservative (Ziemian, 2010).

Two types of built-up members are commonly used for steel bridge construction: closely spaced steel shapes interconnected at intervals using welds or fasteners, and laced or battened members with widely spaced flange components.

up member. The least radius of gyration shall be used in computing the slenderness ratio of each component shape between the connectors.

Lacing, including flat bars, angles, channels, or other shapes employed as lacing, or batten plates shall be spaced so that the slenderness ratio of each component shape between the connectors shall not be more than 75 percent of the governing slenderness ratio of the built-up member.

The nominal compressive resistance of built-up members composed of two or more shapes shall be determined as specified in Article 6.9.4.1 subject to the following modification. If the buckling mode involves relative deformations that produce shear forces in the connectors between individual shapes, $K\ell/r$ shall be replaced by $(K\ell/r)_m$ determined as follows for intermediate connectors that are welded or fully-tensioned bolted:

$$\left(\frac{K\ell}{r}\right)_m = \sqrt{\left(\frac{K\ell}{r}\right)_o^2 + 0.82\left(\frac{\alpha^2}{1+\alpha^2}\right)\left(\frac{a}{r_{ib}}\right)^2} \quad (6.9.4.3.1-1)$$

where:

$\left(\frac{K\ell}{r}\right)_m$ = modified slenderness ratio of the built-up member

$\left(\frac{K\ell}{r}\right)_o$ = slenderness ratio of the built-up member acting as a unit in the buckling direction being considered

a = distance between connectors (in.)

h = distance between centroids of individual component shapes perpendicular to the member axis of buckling (in.)

r_{ib} = radius of gyration of an individual component shape relative to its centroidal axis parallel to the member axis of buckling (in.)

α = separation ratio = $h/2r_{ib}$

6.9.4.3.2—Perforated Plates

Perforated plates shall satisfy the requirements of Articles 6.9.4.2 and 6.8.5.2 and shall be designed for the sum of the shear force due to the factored loads and an additional shear force taken as:

$$V = \frac{P_r}{100} \left(\frac{100}{(\ell/r) + 10} + \frac{8.8(\ell/r)F_y}{E} \right) \quad (6.9.4.3.2-1)$$

where:

V = additional shear force (kip)

P_r = factored compressive resistance specified in Articles 6.9.2.1 or 6.9.2.2 (kip)

The compressive resistance of built-up members is affected by the interaction between the global buckling mode of the member and the localized component buckling mode between lacing points or intermediate connectors. Duan, Reno, and Uang (2002) refer to this type of buckling as compound buckling. For both types of built-up members, limiting the slenderness ratio of each component shape between connection fasteners or welds or between lacing points, as applicable, to 75 percent of the governing global slenderness ratio of the built-up member effectively mitigates the effect of compound buckling (Duan, Reno, and Uang, 2002).

The compressive resistance of both types of members is also affected by any relative deformation that produces shear forces in the connectors between the individual shapes. Eq. 6.9.4.3.1-1 is adopted from AISC (2005) and provides a modified slenderness ratio taking into account the effect of the shear forces. Eq. 6.9.4.3.1-1 applies for intermediate connectors that are welded or fully-tensioned bolted and was derived from theory and verified by test data (Aslani and Goel, 1991). For other types of intermediate connectors on built-up members, including riveted connectors on existing bridges, Eq. C6.9.4.3.1-1 should instead be applied:

$$\left(\frac{K\ell}{r}\right)_m = \sqrt{\left(\frac{K\ell}{r}\right)_o^2 + \left(\frac{a}{r_i}\right)^2} \quad (C6.9.4.3.1-1)$$

where:

r_i = minimum radius of gyration of an individual component shape (in.)

Eq. C6.9.4.3.1-1 is based empirically on test results (Zandonini, 1985). In all cases, the connectors must be designed to resist the shear forces that develop in the buckled member.

Duan, Reno, and Lynch (2000) give an approach for determining the section properties of latticed built-up members, such as the moment of inertia and torsional constant. For additional guidance on the design of lacing and batten plates, refer to AISC (2022b).

- ℓ = member length (in.)
 r = radius of gyration about an axis perpendicular to the perforated plate (in.)
 F_y = specified minimum yield strength (ksi)

In addition to checking the requirements of Article 6.9.4.2.1 for the clear distance between the two longitudinal edge supports of the perforated cover plate utilizing a width-to-thickness ratio limit, λ_r , of $1.86 \sqrt{E/F_y}$, the requirements of Article 6.9.4.2.1 shall also separately be checked for the projecting width from the edge of the perforation to a single longitudinal edge support utilizing a width-to-thickness ratio limit λ_r of $0.45 \sqrt{E/F_y}$.

6.9.4.4—Single-Angle Members

Single angles subject to combined axial compression and flexure about one or both principal axes and satisfying all of the following conditions, as applicable:

- End connections are to a single leg of the angle, and are welded or use a minimum of two bolts;
- The angle is loaded at the ends in compression through the same leg;
- The angle is not subjected to any intermediate transverse loads; and
- If used as web members in trusses, all adjacent web members are attached to the same side of the gusset plate or chord;

may be designed as axially loaded compression members for flexural buckling only according to the provisions of Articles 6.9.2.1, 6.9.4.1.1, and 6.9.4.1.2, provided the following effective slenderness ratio, $(K\ell/r)_{eff}$, is utilized in determining the nominal compressive resistance, P_n :

- For equal-leg angles and unequal-leg angles connected through the longer leg:

- If $\frac{\ell}{r_x} \leq 80$, then:

$$\left(\frac{K\ell}{r}\right)_{eff} = 72 + 0.75 \frac{\ell}{r_x} \quad (6.9.4.4-1)$$

- If $\frac{\ell}{r_x} > 80$, then:

$$\left(\frac{K\ell}{r}\right)_{eff} = 32 + 1.25 \frac{\ell}{r_x} \quad (6.9.4.4-2)$$

C6.9.4.4

Single angles are commonly used as compression members in cross-frames and lateral bracing for steel bridges. Since the angle is typically connected through only one leg, the member is subject to combined axial compression and flexure, or moments about both principal axes due to the eccentricities of the applied axial load. The angle is also usually restrained by differing amounts about its geometric x - and y -axes. As a result, the prediction of the nominal compressive resistance of these members under these conditions is difficult. The provisions contained herein provide significantly simplified provisions for the design of single-angle members satisfying certain conditions that are subject to combined axial compression and flexure. These provisions are based on the provisions for the design of single-angle members used in latticed transmission towers (ASCE, 2000). Similar provisions are also employed in Section E5 of AISC (2022b).

In essence, these provisions permit the effect of the eccentricities to be neglected when these members are evaluated as axially loaded compression members for flexural buckling only using an appropriate specified effective slenderness ratio, $(K\ell/r)_{eff}$, in place of $(K\ell/r_s)$ in Eq. 6.9.4.1.2-1. The effective slenderness ratio indirectly accounts for the bending in the angles due to the eccentricity of the loading allowing the member to be proportioned according to the provisions of Article 6.9.2.1 as if it were a pinned-end concentrically loaded compression member. Furthermore, when the effective slenderness ratio is used, single angles need not be checked for flexural-torsional buckling. The actual maximum slenderness ratio of the angle, as opposed to $(K\ell/r)_{eff}$, is not to exceed the applicable limiting slenderness ratio specified in Article 6.9.3. Thus, if the actual maximum slenderness ratio of the angle exceeds the limiting ratio, a larger angle section must be selected until the ratio is satisfied. If $(K\ell/r)_{eff}$ exceeds the limiting ratio, but the actual maximum slenderness ratio of the angle does not, the design is satisfactory. The limiting

- For unequal-leg angles that are connected through the shorter leg with the ratio of the leg lengths less than 1.7:

- If $\frac{\ell}{r_x} \leq 80$, then:

$$\left(\frac{K\ell}{r}\right)_{eff} = 72 + 0.75 \frac{\ell}{r_x} + 4 \left[\left(\frac{b_t}{b_s}\right)^2 - 1 \right] \geq 0.95 \frac{\ell}{r_z} \quad (6.9.4.4-3)$$

- If $\frac{\ell}{r_x} > 80$, then:

$$\left(\frac{K\ell}{r}\right)_{eff} = 32 + 1.25 \frac{\ell}{r_x} + 4 \left[\left(\frac{b_t}{b_s}\right)^2 - 1 \right] \geq 0.95 \frac{\ell}{r_z} \quad (6.9.4.4-4)$$

where:

- b_t = length of the longer leg of an unequal-leg angle (in.)
- b_s = length of the shorter leg of an unequal-leg angle (in.)
- ℓ = distance between the work points of the joints measured along the length of the angle (in.)
- r_x = radius of gyration about the geometric axis of the angle parallel to the connected leg (in.)
- r_z = radius of gyration about the minor principal axis of the angle (in.)

The actual maximum slenderness ratio of the angle shall not exceed the applicable limiting slenderness ratio specified in Article 6.9.3. Single angles designed using $(K\ell/r)_{eff}$ shall not be checked for flexural-torsional buckling.

ratios specified in Article 6.9.3 are well below the limiting ratio of 200 specified in AISC (2022b).

The expressions for the effective slenderness ratio presume significant end rotational restraint about the y-axis, or the axis perpendicular to the connected leg and gusset plate, as shown in Figure C6.9.4.4-1.

Figure C6.9.4.4-1—Single-Angle Geometric Axes Utilized in the Effective Slenderness Ratio Expressions

As a result, the angle tends to buckle primarily about the x-axis due to the eccentricity of the load about the x-axis coupled with the high degree of restraint about the y-axis (Usami and Galambos, 1971) (Woolcock and Kitipornchai, 1986) (Mengelkoch and Yura, 2002). Therefore, the radius of gyration in the effective slenderness ratio expressions is to be taken as r_x , or the radius of gyration about the geometric axis parallel to the connected leg, and not the minimum radius of gyration r_z about the minor principal axis of the angle. When an angle has significant rotational restraint about the y-axis, the stress along the connected leg will be approximately uniform (Lutz, 1996). Lutz (2006) compared the results from the effective slenderness ratio equations contained herein to test results for single-angle members in compression with essentially pinned-end conditions (Foehl, 1948) (Trahair et al., 1969) and found an average value of P_n/P_{test} of 0.998 with a coefficient of variation of 0.109. A separate set of equations provided in AISC (2022b), which assume a higher degree of x-axis rotational restraint and are thus intended for application only to single angles used as web members in box or space trusses, are not provided herein.

For the case of unequal-leg angles connected through the shorter leg, the limited available test data for this case gives lower capacities for comparable ℓ/r_x values than equal-leg angles (Lutz, 2006). Stiffening the shorter leg rotationally tends to force the buckling axis of the angle away from the x-axis and closer to the z-axis. Thus, $(K\ell/r)_{eff}$ for this case is modified by adding an additional term in Eqs. 6.9.4.4-3 and 6.9.4.4-4, along with a governing slenderness limit based on ℓ/r_z for slender unequal-leg angles. The upper limit on b_t/b_s of 1.7 is

based on the limits of the available physical tests. For an unequal-leg angle connected through the longer leg, note that r_x should be taken as the smaller value about the angle geometric axes, which is typically listed as r_y in AISC (2023).

Single-angle compression members not meeting one or more of the conditions required in this Article, or with leg length ratios b_l/b_s greater than 1.7, should instead be evaluated for combined axial load and flexure as beam-columns according to Section H2 of AISC (2022b). In computing P_n for these cases, the end restraint conditions should be evaluated in calculating the effective length $K\ell$, with the in-plane effective length factor, K , taken equal to 1.0. When the effective length factors about both geometric axes have been computed, the procedures given in Lutz (1992) can be used to obtain a minimum effective radius of gyration for the angle. In determining whether the flexural-torsional buckling resistance of the angle needs to be considered in computing P_n , it is recommended that AISC (2000) be consulted. Also, it has been observed that the actual eccentricity in the angle is less than the distance from the centerline of the gusset if there is any restraint present about the x -axis (Lutz, 1998). In this instance, the eccentricity $\bar{y}$ may be reduced by $t/2$, where t is the thickness of the angle, as long as the angle is on one side of the chord or gusset plate (Woolcock and Kitipornchai, 1986). The nominal flexural resistance of the angle, M_n , for these cases should be determined according to the procedures given in Section F10 of AISC (2022b).

Single-angle members are often employed in X-type configurations in cross-frames. It has been suggested (ASCE, 2000) that for cases in such configurations, where one diagonal is in tension with a force not less than 20 percent of the force in the diagonal compression member, that the crossover or intersection point may be considered as a brace point for out-of-plane buckling. A different approach has been suggested for equally loaded compression and tension diagonals in X-type configurations in which all connections are welded (El-Tayem and Goel, 1986), which also assumes a significant level of restraint at the crossover point. While such approaches could potentially be utilized in determining the effective slenderness ratio, they have not yet received extensive validation and the assumed level of restraint may not actually be present in certain instances. For example, should the members be connected with only a single bolt at the crossover point, the necessary rotational restraint about the y -axis assumed in the effective slenderness ratio equations may not be present at that point. Thus, it is recommended herein in the interim that the effective slenderness ratio equations be conservatively applied to single-angle compression members used in X-type bracing configurations by using the full length of the diagonal between the connection work points for ℓ .

6.9.4.5—Plate-Buckling under Service and Construction Loads

The provisions contained herein shall not apply at the service limit state or during construction for webs of:

- composite or noncomposite I-section members subject to flexure only,
- composite box-section members subject to flexure only, and
- noncomposite box-section members subject to flexure only, containing longitudinally unstiffened webs or webs with only one longitudinal stiffener.

Such members shall be checked for web bend-buckling at these limit states according to the applicable provisions of Articles 6.10 and 6.11, respectively, using the appropriate web bend-buckling resistance, F_{crw} , specified in Article 6.10.1.9.

The provisions contained herein also shall not apply for plate elements supported only along one longitudinal edge and for walls of circular tubes.

All other

- slender plate elements, as defined in Article 6.9.4.2.2a, or
- slender longitudinally stiffened plate panels, as defined in Article E6.1.2,

subjected to longitudinal compressive stress at one or both of their longitudinal edges, shall satisfy the following at the service limit state and for constructibility:

$$f_c \leq \frac{0.9Ek}{\lambda^2} \leq F_y \quad (6.9.4.5-1)$$

in which:

- λ = slenderness, b_f/t_f , w/t_f , or D/t_w , of the slender flange or web plate element or longitudinally stiffened plate panel under consideration, as applicable
- f_c = maximum longitudinal compressive stress (ksi) acting on the gross cross-section in the plate element or longitudinally stiffened plate panel under consideration due to:

- The Service II loads;
- The factored load for constructibility as specified in Article 3.4.2.1.

For noncomposite box-section members, the flange areas of the gross cross-section shall be reduced to account for shear lag, as applicable, in

C6.9.4.5

The checks specified herein are not required at the service limit state and for constructibility for plate elements supported only along one longitudinal edge, webs of I-section and box-section members specified herein that are subject to flexure only, or for the walls of circular tubes. The slenderness or plate-buckling response of these types of elements is typically limited by other design provisions, which may be less restrictive in some cases, and/or the post-buckling response is not considered to be of any negative consequence.

Since significant post-buckling resistance is often assumed at the strength limit state in computing the nominal flexural and axial compressive resistance of members with cross-sections containing slender plate elements supported along two longitudinal edges and/or longitudinally stiffened plates supported along their two longitudinal edges and containing slender plate panels, such members must satisfy the provisions of this article to ensure that theoretical local buckling of those plate elements or panels does not occur at the service limit state and for constructibility. Eq. 6.9.4.5-1 is used to check for theoretical local buckling at these limit states under the net combined normal stresses acting on each of these types of plate elements or panels subjected to compressive stress.

The influence of combined normal and shear stresses on theoretical plate-buckling at the service limit state and for constructibility is not considered in these Specifications. Satisfaction of specified requirements to separately prevent theoretical buckling under normal stresses and under shear stresses is considered sufficient as an approximate technique to control plate bending strains and transverse displacements. In experimental tests, noticeable plate bending deformations and associated transverse displacements can occur from the onset of load application due to initial plate out-of-flatness. Because of stable plate post-buckling behavior, there is no significant change in the rate of increase of the transverse displacements as the theoretical plate-buckling stress is exceeded. Due to unavoidable geometric imperfections, the plate-buckling behavior is a load-deflection problem rather than a bifurcation problem. Satisfaction of the specified requirements to prevent

the calculation of the stresses due to flexure, as specified in Article 6.12.2.2.2g.

theoretical buckling helps limit the magnitude of the corresponding transverse displacements.

Plate local buckling is not checked at the fatigue limit state in these provisions because the plate buckling check under the Service II loads will tend to control over a similar check under the unfactored permanent load plus the Fatigue I load combination.

Any box-section member plate element subjected to stress due to bending about a principal axis of the box parallel to the plate is considered as a flange plate element for bending about that axis. Any member plate element subjected to flexural shear orthogonal to the axis of bending, and/or nominally linearly varying normal stresses due to bending about an axis normal to the face of the plate, is considered as a web plate element. It should be noted that in box-section members, the flange plate elements associated with one direction of bending are the web plate elements associated with the other direction of bending, and vice versa. Therefore, for members subjected to biaxial bending, the same elements are designed as a web plate element for bending in one direction, and as a flange plate element for bending in the other direction.

The plate-buckling coefficient, k , given by Eqs. 6.9.4.5-2 through 6.9.4.5-4 is from CEN (2006). These equations address general loading conditions from any combination of axial compression and bending within the plane of the plates for the evaluation of longitudinally unstiffened plates and longitudinally stiffened plate panels. They are based on the idealization of general plates and plate panels as having simply supported boundary edge conditions. The ratio f_1/f_2 is less than or equal to 1.0 in all cases, since f_1 is the smaller edge stress. The stress f_1 may be a smaller compressive value compared to f_2 , or it may be a tensile stress, in which case f_1 is taken as a negative value. The ratio f_1/f_2 is positive when both f_1 and f_2 are in compression, and it is negative when f_1 is in tension. For unusual cases where the ratio of f_1/f_2 is smaller than -3, buckling of the plate is unlikely. In this case, it is conservative to use k equal to 96.

A plate-buckling coefficient of $k = 4.0$ may be employed conservatively in Eq. 6.9.4.5-1 as an initial design check. Web plate elements in noncomposite box-section members subjected predominantly to flexure often may require the larger k values from Eqs. 6.9.4.5-2 through 6.9.4.5-4 to satisfy the requirement of Eq. 6.9.4.5-1.

k = plate-buckling coefficient, considering any gradient in the longitudinal stress calculated as follows:

- If $1.0 \geq \frac{f_1}{f_2} \geq 0.0$, then:

$$k = \frac{8.2}{1.05 + \frac{f_1}{f_2}} \quad (6.9.4.5-2)$$

- If $0.0 > \frac{f_1}{f_2} \geq -1.0$, then:

$$k = 7.81 - 6.29 \frac{f_1}{f_2} + 9.78 \left(\frac{f_1}{f_2} \right)^2 \quad (6.9.4.5-3)$$

- If $-1.0 > \frac{f_1}{f_2} \geq -3.0$, then:

$$k = 5.98 \left(1 - \frac{f_1}{f_2} \right)^2 \quad (6.9.4.5-4)$$

where:

b_f = total inside width between the plate elements providing lateral restraint to the longitudinal edges of the flange plate element under consideration (in.)

D = total inside width between the plate elements providing lateral restraint to the longitudinal edges of the web plate element under consideration (in.)

- f_1 = smaller longitudinal stress at the longitudinal edges of the plate element or longitudinally stiffened plate panel at the cross-section under consideration, taken as positive in compression and negative in tension (ksi)
- f_2 = larger longitudinal compressive stress at the longitudinal edges of the plate element or longitudinally stiffened plate panel at the cross-section under consideration, taken as positive (ksi)
- F_y = specified minimum yield strength of the plate element or longitudinally stiffened plate panel under consideration (ksi)
- t_f = thickness of the flange plate element or longitudinally stiffened flange plate panel under consideration (in.)
- t_w = thickness of the web plate element under consideration (in.)
- w = width of the plate between the centerlines of the individual longitudinal stiffeners or between the centerline of the longitudinal stiffener and the inside of the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration, as applicable (in.)

Refer to Figure CE6.1.3-1 for further information on the definition of the variable, w , for longitudinally stiffened plates.

For constructibility, the resistance side of Eq. 6.9.4.5-1 shall be multiplied by the resistance factor for flexure, ϕ_f , specified in Article 6.5.4.2.

6.9.5—Composite Members

6.9.5.1—Nominal Compressive Resistance

The provisions of this Article shall apply to composite columns without flexure. The provisions of Article 6.12.2.3 shall apply to composite columns in flexure. The provisions of Articles 6.9.6 and 6.12.2.3.3 provide an alternative for the design of composite concrete-filled steel tubes (CFSTs) subject to axial compression or combined axial compression and flexure.

The nominal compressive resistance of a composite column satisfying the provisions of Article 6.9.5.2 shall be taken as:

- If $\lambda \leq 2.25$, then:

$$P_n = 0.66^{\lambda} F_c A_s \quad (6.9.5.1-1)$$

- If $\lambda > 2.25$, then:

$$P_n = \frac{0.88 F_c A_s}{\lambda} \quad (6.9.5.1-2)$$

in which:

λ = normalized column slenderness factor

C6.9.5.1

The procedure for the design of composite columns is the same as that for the design of steel columns, except that the specified minimum yield strength of structural steel, the modulus of elasticity of steel, and the radius of gyration of the steel section are modified to account for the effect of concrete and of longitudinal reinforcing bars. Explanations of the origin of these modifications and comparison of the design procedure, with the results of numerous tests, may be found in SSRC Task Group 20 (1979) and Galambos and Chapuis (1980).

where:

P_e = Euler buckling load (kip)

6.9.5.2—Limitations

6.9.5.2.1—General

The compressive resistance shall be calculated in accordance with Article 6.9.5.1 if the cross-sectional area of the steel section comprises at least four percent of the total cross-sectional area of the member.

The compressive resistance shall be calculated as a reinforced concrete column under Section 5 if the cross-sectional area of the shape or tube is less than four percent of the total cross-sectional area.

The compressive strength of the concrete shall be between 3.0 ksi and 8.0 ksi.

The specified minimum yield strength of the steel section and the longitudinal reinforcement used to calculate the nominal compressive resistance shall not exceed 60.0 ksi.

The transfer of all load in the composite column shall be considered in the design of supporting components.

The cross-section shall have at least one axis of symmetry.

6.9.5.2.2—Concrete-Filled Tubes

The wall thickness requirements for unfilled tubes specified in Article 6.9.4.2 shall apply to filled composite tubes.

6.9.5.2.3—Concrete-Encased Shapes

Concrete-encased steel shapes shall be reinforced with longitudinal and lateral reinforcement. The reinforcement shall conform to the provisions of Article 5.6.4.6, except that the vertical spacing of lateral ties shall not exceed the least of:

- 16 longitudinal bar diameters,
- 48 tie bar diameters, or
- 0.5 of the least side dimension of the composite member.

Multiple steel shapes in the same cross-section of a composite column shall be connected to one another with lacing and tie plates to prevent buckling of individual shapes before hardening of the concrete.

6.9.6—Composite Concrete-Filled Steel Tubes (CFSTs)

6.9.6.1—General

The provisions of this Article, along with Article 6.12.2.3.3, provide an alternative method for the design of composite CFSTs with or without internal reinforcement subject to axial compression or for

C6.9.5.2.1

Little of the test data supporting the development of the present provisions for design of composite columns involved concrete strengths in excess of 6.0 ksi. Normal weight concrete was believed to have been used in all tests. A lower limit of 3.0 ksi is specified to encourage the use of good-quality concrete.

C6.9.5.2.3

Concrete-encased shapes are not subject to the width/thickness limitations specified in Article 6.9.4.2 because it has been shown that the concrete provides adequate support against local buckling.

C6.9.6.1

CFSTs are primarily used for piles, drilled shafts, piers or columns, and other structural members subject to significant compression only or significant compression and flexure. The provisions for the design of composite

combined axial compression and flexure. CFSTs should not be used as pure flexural members. CFSTs expected to develop full plastic hinging of the composite section as a result of a seismic event shall satisfy the provisions of the *AASHTO Guide Specifications for LRFD Seismic Bridge Design*.

CFSTs contained herein may be used as an alternative to the provisions of Articles 6.9.5 and 6.12.2.3.2, which are intended for applications where full composite action is not deemed necessary. Research demonstrates that Articles 6.9.5 and 6.12.2.3.2 do not assure full composite action (Robinson et al., 2012) (Lehman and Roeder, 2012). Extensive research on composite CFSTs has been completed since the provisions of Article 6.9.5 were developed (Goode and Lam, 2011) (Gourley et al., 2001). The provisions specified in Article 6.9.6 reflect the results of much of that research, reduce uncertainty and increase the accuracy of the prediction of the engineering properties of these members, and are similar to the AISC (2022b) CFST provisions. Seismic design examples demonstrating the application of these provisions are contained in Kenarangi and Bruneau (2017).

Experiments show that the resistance provided by the steel tube is much greater than that provided by internal reinforcement because the tube has a larger moment arm (Roeder and Lehman, 2012).

6.9.6.2—Limitations

The following requirements shall be satisfied:

- Circular steel tubes shall be used.
- Spiral-welded tubes formed from coil steel, straight-seam welded tubes formed from flat plates, or seamless pipes shall be used.
- Steel tubes with straight seam welds shall be permitted for CFSTs for all applications where the outside diameter is 24.0 in. or less. Steel tubes with straight seam welds shall also be permitted for tubes larger than 24.0 in. in diameter. For straight seam tubes with diameters over 24.0 in., consideration should be given to the use of a low-shrinkage admixture to achieve a maximum of 0.04 percent shrinkage at 28 days, as tested in accordance with ASTM C157/C157M, or to providing a shear transfer mechanism such as shear rings.
- The wall thickness of the steel tube shall satisfy:

$$\frac{D}{t} \leq 0.15 \frac{E}{F_{yst}} \quad (6.9.6.2-1)$$

where:

- D = outside diameter of the steel tube (in.)
- E = elastic modulus of steel tube (ksi)
- F_{yst} = specified minimum yield strength of steel tube (ksi)
- t = wall thickness of the steel tube (in.)

C6.9.6.2

Circular CFSTs provide continuous confinement of the concrete, which is superior to that achieved with rectangular CFSTs. Rectangular steel tubes are not included in these provisions.

Large-diameter tubes are required for most components in bridge applications. These are commonly formed by one of two methods. Coil steel may be unrolled in a helical fashion to form a spiral-welded tube. The spiral welds are made as butt joints and formed from both the inside and outside of the tube by the double submerged arc process. The spiral welds are subjected to direct stresses under axial load and flexure, and therefore they are essential for developing CFST resistance. Good performance is assured if proper weld metal and processes are employed and the minimum tensile strength of the weld metal matches the yield strength of the steel tube. The welds may also be inspected by ultrasonic or radiographic methods over the entire length of the weld if increased quality control is needed. This spiral weld process is limited to tubes with wall thickness of about 1.0 in. or less and diameters greater than about 20.0 in. Minimum requirements for these welds are provided in ASTM A252/A252M and API Specification 5L, as appropriate.

The limiting diameter-to-thickness ratio given by Eq. 6.9.6.2-1 is commonly used for CFSTs and is the design limit for a compact composite section as specified in AISC (2022b) for CFSTs. This limit has been shown to allow CFSTs to achieve the full plastic capacity while also providing substantial inelastic deformation capacity (Roeder, Lehman, and Bishop, 2010). CFST piles may require a larger thickness than that suggested by Eq. 6.9.6.2-1 as a result of driving requirements.

The limits on the compressive strength of the concrete to the yield stress on the steel are required

- The specified minimum 28-day compressive strength of the concrete shall be the greater of 3.0 ksi and $0.075F_{ywf}$.

because research has shown that the benefits of composite action are reduced outside these limits.

Research shows that two mechanisms, mechanical transfer caused by slight projection of the spiral weld into the concrete fill and friction caused by contact stress between the steel and concrete, provide bond transfer between the steel tube and the concrete fill. For large-diameter, straight seam tubes, there has been concern that shrinkage of the concrete could compromise the composite behavior although the research results are not definitive. The use of a low-shrinkage admixture is thought to enhance the bond capacity, particularly for larger diameter tubes. The detrimental effects of shrinkage would be less significant with smaller diameter tubes. In addition, binding action resulting from bending enhances bond shear stress transfer between the steel tube and the concrete fill. This binding action assures adequate shear transfer without any internal connectors.

Results of research (Kenarangi and Bruneau, 2017) indicate that composite action between the tube and concrete fill occurs under lateral loading even when the inner diameter surface of the tube was contaminated with mud and bentonite clay. Only a thick layer of grease was found to disrupt the connection sufficiently to prevent composite action at the strength limit state. For the case of large-diameter straight seam tubes, where previous research had indicated less robust composite action, adding shear rings or similar positive shear transfer mechanisms provide an alternative to the use of low-shrinkage admixtures. Kenarangi and Bruneau (2017) provide design equations for shear rings.

6.9.6.3—Combined Axial Compression and Flexure

6.9.6.3.1—General

The axial compressive load, P_u , and concurrent moment, M_u , calculated for the factored loadings by elastic analytical procedures shall satisfy the factored stability-based P-M interaction relationship. The factored interaction resistance curve shall be developed by applying the resistance factor, ϕ_c , for combined axial compression and flexure in composite CFSTs specified in Article 6.5.4.2 to the nominal stability-based P-M interaction curve as specified in Article 6.9.6.3.4.

C6.9.6.3.1

The stability-based P-M interaction relationship can be determined by either the plastic stress distribution method (PSDM) or the strain compatibility method (SCM). The PSDM is an analysis method in which the nominal flexural composite resistance of the CFST in the presence of axial load is determined from a cross-sectional analysis using the constituent materials based on equilibrium at full plastification of the section, and is recommended herein. The computed resistance is then later adjusted for stability of the member through the development of a stability-based interaction curve.

An analysis of a database of experiments shows that using standard models, the strength prediction for composite CFSTs has a co-variance of 0.05 when axial loads are less than $0.6P_o$, where P_o is defined in Article 6.9.6.3.2. Further, circular CFST members have higher and more uniformly distributed confining stresses, which provide increased compressive strength and deformability of the fill concrete relative to reinforced concrete sections with discrete spiral confinement.

6.9.6.3.2—Axial Compressive Resistance

The factored resistance, P_r , of a composite CFST column subject to axial compression shall be determined as:

$$P_r = \phi_c P_n \quad (6.9.6.3.2-1)$$

where:

- ϕ_c = resistance factor for axial compression and combined axial compression and flexure in composite CFSTs specified in Article 6.5.4.2
- P_n = nominal compressive resistance (kip)

The nominal resistance, P_n , of a composite CFST column subject to axial compression shall be determined using Eqs. 6.9.6.3.2-2 through 6.9.6.3.2-7 as follows:

- If $\frac{P_o}{P_e} \leq 2.25$, then:

$$P_n = \left[0.658 \left(\frac{P_o}{P_e} \right) \right] P_o \quad (6.9.6.3.2-2)$$

- Otherwise:

$$P_n = 0.877 P_e \quad (6.9.6.3.2-3)$$

in which:

$$P_o = 0.95 f'_c A_c + F_{yst} A_{st} + F_{yb} A_{sb} \quad (6.9.6.3.2-4)$$

$$P_e = \frac{\pi^2 EI_{eff}}{(K\ell)^2} \quad (6.9.6.3.2-5)$$

$$EI_{eff} = EI_{st} + EI_{sl} + C'E_c I_c \quad (6.9.6.3.2-6)$$

$$C' = 0.15 + \frac{P}{P_o} + \frac{A_{st} + A_{sb}}{A_{st} + A_{sb} + A_c} \leq 0.9 \quad (6.9.6.3.2-7)$$

where:

- A_{st} = cross-sectional area of the steel tube (in.²)
- A_{sb} = total cross-sectional area of the internal reinforcement bars (in.²)
- A_c = net cross-sectional area of the concrete (in.²)
- E_c = elastic modulus of the concrete (ksi)
- E = elastic modulus of the steel tube and the internal steel reinforcement (ksi)
- EI_{eff} = effective composite flexural cross-sectional stiffness of the CFST (kip-in.²)
- F_{yb} = specified minimum yield strength of the internal steel reinforcing bars (ksi)

C6.9.6.3.2

The procedure for designing composite CFST columns subject to axial compression is similar to that used for the design of steel columns, except that a composite resistance and effective flexural stiffness, EI_{eff} , are employed. The effective flexural stiffness increases with increasing compressive load, which suppresses cracking in the concrete fill, and therefore, C' is a function of the axial load. The flexural stiffness values provided by Eqs. 6.9.6.3.2-6 and 6.9.6.3.2-7 correspond to approximately 90 percent of the maximum resistance of the member, which provides a conservative estimate of the buckling capacity. The flexural stiffness equations have been developed by comparison with past experimental results on composite CFSTs where the members have been loaded to loss of lateral load-carrying capacity. Experiments show that this estimate is more accurate with smaller variance or standard deviation than that provided by other commonly used methods (Marson and Bruneau, 2004) (Roeder, Lehman, and Bishop, 2010).

- F_{yt} = specified minimum yield strength of the steel tube (ksi)
 f'_c = specified minimum 28-day compressive strength of the concrete (ksi)
 I_c = uncracked moment of inertia of the concrete about the centroidal axis (in.⁴)
 I_{st} = moment of inertia of the internal steel reinforcement about the centroidal axis (in.⁴)
 I_{st} = moment of inertia of the steel tube about the centroidal axis (in.⁴)
 K = effective length factor as specified in Article 4.6.2.5
 ℓ = unbraced length of the column (in.)
 P = unfactored axial dead load (kip)
 P_e = elastic critical buckling resistance for flexural buckling (kip)
 P_n = nominal compressive resistance (kip)
 P_o = compressive resistance of the column without consideration of buckling (kip)

6.9.6.3.3—Nominal Flexural Composite Resistance

The nominal flexural composite resistance, M_n , of circular CFSTs as a function of the nominal axial resistance, P_n , shall be determined as specified in Article 6.12.2.3.3.

6.9.6.3.4—Nominal Stability-Based Interaction Curve

The stability-based P-M interaction curve of CFSTs shall be constructed by joining points A' , A'' , D , and B , as illustrated in Figure 6.9.6.3.4-1, where:

- Point A corresponds to P_o , determined as specified in Article 6.9.6.3.2.
- Point A' corresponds to the axial compression resistance without moment, P_n , determined as specified in Article 6.9.6.3.2.
- Point A'' is the intersection of the material-based interaction curve determined as specified in Article C6.12.2.3.3 and a horizontal line through Point A' .
- Point B corresponds to the composite plastic moment resistance without an axial load, M_o , determined as specified in Article C6.12.2.3.3.
- Point C corresponds to the axial force, P_C , on the material-based interaction curve determined as specified in Article C6.12.2.3.3 that corresponds to the composite plastic moment resistance without axial load, M_o (Point B).
- Point D is located on the material-based interaction curve determined as specified in Article C6.12.2.3.3 and is taken as the axial load, P_D , determined as:

$$P_D = 0.5P_C \frac{P_n}{P_o} \quad (6.9.6.3.4-1)$$

where P_n is determined as specified in Article 6.9.6.3.2.

C6.9.6.3.4

The stability-based P-M interaction curve shown in Figure 6.9.6.3.4-1 includes stability effects and is a modified version of the PSDM material interaction curve shown in Figure C6.12.2.3.3-2, where the modification is based on the buckling load computed from Eqs. 6.9.6.3.2-2 or 6.9.6.3.2-3. This interaction curve is used for determining the nominal resistance of the composite CFST for combined axial compression and flexure for all load conditions (Moon et al., 2013).

Figure 6.9.6.3.4-1—Construction of the Normalized Stability-based P-M Interaction Curve

6.10—I-SECTION FLEXURAL MEMBERS

6.10.1—General

The provisions of this Article apply to flexure of rolled or fabricated straight, kinked (chorded) continuous, or horizontally curved steel I-section members symmetrical about the vertical axis in the plane of the web. These provisions cover the design of composite and noncomposite sections, hybrid and nonhybrid sections, and constant and variable web depth members as defined by and subject to the requirements of Articles 6.10.1.1 through 6.10.1.8. The provisions also cover the combined effects of major-axis bending and flange lateral bending from any source.

All types of I-section flexural members shall be designed as a minimum to satisfy:

- The cross-section proportion limits specified in Article 6.10.2;
- The constructibility requirements specified in Article 6.10.3;
- The service limit state requirements specified in Article 6.10.4;
- The fatigue and fracture limit state requirements specified in Article 6.10.5;
- The strength limit state requirements specified in Article 6.10.6.

The web bend-buckling resistance in slender web members shall be determined as specified in Article 6.10.1.9. Flange-strength reduction factors in hybrid and/or slender web members shall be determined as specified in Article 6.10.1.10.

Cross-frames and diaphragms for I-sections shall satisfy the provisions of Article 6.7.4. Where required, lateral bracing for I-sections shall satisfy the provisions of Article 6.7.5.

The pitch of the fasteners in the compression and tension flanges of built-up I-section flexural members

C6.10.1

This Article addresses general topics that apply to all types of steel I-sections in straight bridges, horizontally curved bridges, or bridges containing both straight and curved segments. For the application of the provisions of Article 6.10, bridges containing both straight and curved segments are to be treated as horizontally curved bridges since the effects of curvature on the support reactions and girder deflections, as well as the effects of flange lateral bending, usually extend beyond the curved segments. Note that kinked (chorded) girders exhibit the same actions as curved girders, except that the effect of the noncollinearity of the flanges is concentrated at the kinks. Continuous kinked (chorded) girders should be treated as horizontally curved girders with respect to these Specifications.

The five bullet items in this Article indicate the overarching organization of the subsequent provisions for the design of straight I-section flexural members. Each of the subarticles throughout Article 6.10 are written such that they are largely self-contained, thus minimizing the need for reference to multiple Articles to address any one of the essential design considerations. For the strength limit state, Article 6.10.6 directs the Engineer to the subsequent Articles 6.10.7 through 6.10.12, and optionally for sections in straight I-girder bridges only, to Appendixes A6 and B6, for the appropriate design requirements based on the type of I-section. The specific provisions of these Articles and Appendixes are discussed in the corresponding Articles of the Commentary.

The provisions of Article 6.10 and the optional Appendixes A6 and B6 provide a unified approach for consideration of combined major-axis bending and flange lateral bending from any source. For the majority of straight nonskewed bridges, flange lateral bending effects tend to be most significant during construction and tend to be insignificant in the final constructed condition.

should satisfy the maximum pitch requirements for stitch bolts in built-up compression members and tension members, respectively, specified in Article 6.13.2.6.3.

Significant flange lateral bending may be caused by wind, by torsion from eccentric concrete deck overhang loads acting on cantilever-forming brackets placed along exterior girders, and by the use of discontinuous cross-frames, i.e., not forming a continuous line between multiple girders, in conjunction with skews exceeding 20 degrees. In these cases, the flange lateral bending may be considered at the discretion of the Engineer. Although the use of refined analysis methods is not required in order to fulfill the requirements of these provisions, these methods, when utilized, do allow for consideration of these effects. The intent of the Article 6.10 provisions is to permit the Engineer to consider flange lateral bending effects in the design in a direct and rational manner should they be judged to be significant. In the absence of calculated values of f_t from a refined analysis, a suggested estimate for the total unfactored f_t in a flange at a cross-frame or diaphragm due to the use of discontinuous cross-frame or diaphragm lines at or near supports, but not along the entire length of the bridge, is 10.0 ksi for interior girders and 7.5 ksi for exterior girders. These estimates are based on a limited examination of refined analysis results for bridges with skews approaching 60 degrees from normal and an average D/b_f ratio of approximately 4.0. In regions of the girders with contiguous cross-frames or diaphragms, these values need not be considered. Lateral flange bending in the exterior girders is substantially reduced when cross-frames or diaphragms are placed in discontinuous lines over the entire bridge due to the reduced cross-frame or diaphragm forces. A value of 2.0 ksi is suggested for f_t for the exterior girders in such cases, with the suggested value of 10 ksi retained for the interior girders. In all cases, it is suggested that the recommended values of f_t be proportioned to dead and live load in the same proportion as the unfactored major-axis dead and live load stresses at the section under consideration. An examination of cross-frame or diaphragm forces is also considered prudent in all bridges with skew angles exceeding 20 degrees. When all the above lateral bending effects are judged to be insignificant or incidental, the flange lateral bending term, f_t , is simply set equal to zero in the appropriate equations. The format of the equations then reduces simply to the more conventional and familiar format for checking the nominal flexural resistance of I-sections in the absence of flange lateral bending.

For horizontally curved bridges, in addition to the potential sources of flange lateral bending discussed previously, flange lateral bending effects due to curvature must always be considered at all limit states and also during construction.

White et al. (2012) present one method of estimating I-girder flange lateral bending stresses in straight skewed I-girder bridges and curved I-girder bridges with or without skew. This method is particularly useful to calculate these stresses when using a grid or plate and

eccentric beam analysis since these results cannot be obtained directly from such analyses.

Flowcharts for flexural design of I-section members are provided in Appendix C6. Fundamental calculations for flexural members have been placed in Appendix D6.

6.10.1.1—Composite Sections

Sections consisting of a concrete deck that provides proven composite action and lateral support connected to a steel section by shear connectors designed according to the provisions of Article 6.10.10 shall be considered composite sections.

6.10.1.1.1—Stresses

6.10.1.1.1a—Sequence of Loading

The elastic stress at any location on the composite section due to the applied loads shall be the sum of the stresses caused by the loads applied separately to the:

- steel section,
- short-term composite section, and
- long-term composite section.

For unshored construction, permanent load applied before the concrete deck has hardened or is made composite shall be assumed carried by the steel section alone; permanent load and live load applied after this stage shall be assumed carried by the composite section. For shored construction, all permanent load shall be assumed applied after the concrete deck has hardened or has been made composite and the contract documents shall so indicate.

6.10.1.1.1b—Stresses for Sections in Positive Flexure

For calculating flexural stresses within sections subjected to positive flexure, the composite section shall consist of the steel section and the transformed area of the effective width of the concrete deck. Concrete on the tension side of the neutral axis shall not be considered effective at the strength limit state.

For transient loads assumed to be applied to the short-term composite section, the concrete deck area shall be transformed by using the short-term modular ratio, n . For permanent loads assumed applied to the long-term composite section, the concrete deck area shall be transformed by using the long-term modular ratio, $3n$. Where moments due to the transient and permanent loads are of opposite sign at the strength limit state, the associated composite section may be used with each of these moments if the resulting net stress in the concrete deck due to the sum of the unfactored moments is compressive. Otherwise, the provisions of Article 6.10.1.1.1c shall be used to determine the stresses

C6.10.1.1.1a

While shored construction is permitted according to these provisions, its use is not recommended. There has been limited research on the effects of concrete creep on composite steel girders under large dead loads. Also, there have been only a very limited number of demonstration bridges built with shored construction in the U.S. Furthermore, there is an increased likelihood of significant tensile stresses occurring in the concrete deck at permanent interior supports of continuous spans when shored construction is used. These provisions may not be sufficient for shored construction where close tolerances on the girder cambers are important.

in the steel section. Stresses in the concrete deck shall be determined as specified in Article 6.10.1.1.1d.

The modular ratio should be taken as:

$$n = \frac{E}{E_c} \quad (6.10.1.1.1b-1)$$

where:

E_c = modulus of elasticity of the concrete determined as specified in Article 5.4.2.4 (ksi)

6.10.1.1.1c—Stresses for Sections in Negative Flexure

For calculating flexural stresses in sections subjected to negative flexure, the composite section for both short-term and long-term moments shall consist of the steel section and the longitudinal reinforcement within the effective width of the concrete deck, except as specified otherwise in Articles 6.6.1.2.1, 6.10.1.1.1d, or 6.10.4.2.1.

6.10.1.1.1d—Concrete Deck Stresses

For calculating longitudinal flexural stresses in the concrete deck due to all permanent and transient loads, the short-term modular ratio, n , shall be used.

C6.10.1.1.1d

When the deck stresses due to short-term and permanent loads are of the same sign, the n section generally governs the deck stress calculation. Also, the maximum combined compression in the deck typically occurs at a section where the permanent and short-term stresses are additive. However, when considering the length of the deck over which the provisions of Article 6.10.1.7 are to be applied, smaller compressive permanent load stresses can result in larger net tensile stresses in the deck in the vicinity of inflection point locations. In these situations, use of the $3n$ section for the permanent load stresses produces the more critical tension stress in the deck. This level of refinement in the calculation of the deck longitudinal tension stresses is considered unjustified.

6.10.1.1.1e—Effective Width of Concrete Deck

The effective width of the concrete deck shall be determined as specified in Article 4.6.2.6.

6.10.1.2—Noncomposite Sections

Sections where the concrete deck is not connected to the steel section by shear connectors designed in accordance with the provisions of Article 6.10.10 shall be considered noncomposite sections.

C6.10.1.2

Noncomposite sections are not recommended, but are permitted.

6.10.1.3—Hybrid Sections

The specified minimum yield strength of the web should not be less than the larger of 70 percent of the specified minimum yield strength of the higher-strength flange and 36.0 ksi.

For members with a higher-strength steel in the web than in one or both flanges, the yield strength of the web

C6.10.1.3

Hybrid sections consisting of a web with a specified minimum yield strength lower than that of one or both of the flanges may be designed with these Specifications. Although these provisions can be safely applied to all types of hybrid sections (ASCE, 1968), it is recommended that the difference in the specified

shall not be taken greater than 120 percent of the specified minimum yield strength of the lower-strength flange in determining the flexural and shear resistance. Composite girders in positive flexure with a higher-strength steel in the web than in the compression flange may use the full web strength in determining their flexural and shear resistance.

minimum yield strengths of the web and the higher-strength flange preferably be limited to one steel grade. Such sections generally are believed to have greater design efficiency. For these types of sections, the upper limit of F_{yw} on the value of F_{yf} , determined in Articles 6.10.8.2.2, 6.10.8.2.3, A6.3.2, or A6.3.3 as applicable, does not govern. Furthermore, as discussed in Article C6.10.1.9.1, this minimum limit on the web yield strength guards against early inelastic web bend-buckling of slender hybrid webs.

A number of the curved noncomposite I-girders tested by Mozer and Culver (1970) and Mozer et al. (1971) had F_{yw}/F_{yf} between 0.72 and 0.76. The flexural and shear strengths of these hybrid I-girders are predicted adequately by these Specifications, including the development of shear strengths associated with tension-field action. The major-axis bending stresses tend to be smaller in curved I-girder webs compared to straight I-girder webs, since part of the flexural resistance is taken up by flange lateral bending. The provisions of Articles 6.10.2 and 6.10.5.3 prevent significant out-of-plane flexing of the web in straight and curved hybrid I-girders (Yen and Mueller, 1966) (ASCE, 1968).

Test data for sections with nominally larger yield strengths in the web than in one or both flanges are limited. Nevertheless, in many experimental tests, the actual yield strength of the thinner web is larger than that of the flanges. The nominal yield strength that may be used for the web in determining the flexural and shear resistance for such cases is limited within these Specifications to a range supported by the available test data.

6.10.1.4—Variable Web Depth Members

The effect of bottom flange inclination shall be considered in determining the bottom flange stress caused by bending about the major axis of the cross-section, and any potential modifications to the vertical web shear. In cases where static equilibrium permits the vertical web shear to be reduced in variable web depth members, only the web dead-load shear may be reduced by the vertical component of the bottom flange force.

At points where the bottom flange becomes horizontal, full- or partial-depth transverse stiffening of the web shall be provided, unless the provisions of Article D6.5.2 are satisfied for the factored vertical component of the inclined flange force using a length of bearing N equal to zero.

C6.10.1.4

If the normal stress in an inclined bottom flange, calculated without consideration of flange lateral bending, is determined by simply dividing the bending moment about the major axis of the cross-section by the elastic section modulus, this stress is generally underestimated. The normal stress within an inclined bottom flange may be determined by first calculating the horizontal component of the flange force required to develop this bending moment as:

$$P_h = M A_f / S_x \quad (\text{C6.10.1.4-1})$$

where:

- A_f = area of the inclined bottom flange (in.²)
- M = bending moment about the major axis of the cross-section at the section under consideration (kip-in.)
- S_x = elastic section modulus to the inclined bottom flange (in.³)

For composite sections, the provisions of Article 6.10.1.1a are to be applied in computing P_h . The

normal stress in the inclined flange, f_n , may then be determined as (Blodgett, 1982):

$$f_n = \frac{(P_h / A_f)}{\cos \theta} \quad (\text{C6.10.1.4-2})$$

where:

θ = angle of inclination of the bottom flange (degrees)

The corresponding vertical component of the flange force, P_v , may be determined as:

$$P_v = P_h \tan \theta \quad (\text{C6.10.1.4-3})$$

This component of the flange force affects the vertical web shear. In regions of positive flexure with tapered or parabolic haunches sloping downward toward the supports, the vertical web shear is increased by P_v . For fish belly haunches, $P_v = 0$ near interior supports because the slope of the bottom flange is small in that area. For all other cases, the vertical web shear is reduced by P_v . In cases where the vertical web shear is reduced, the Specifications permit the Engineer to reduce the web dead-load shear accordingly. Calculation of the reduced live-load shear is problematic because numerous sets of concurrent moments and shears must be evaluated in order to determine the critical or smallest shear reduction, and thus is not likely worth the effort. Also, variable depth webs are used most often on longer-span girders where dead load is more predominant. The total modified vertical web shear may be used in the design of the sloping flange-to-web welds.

In fish belly haunches, where the slope of the bottom flange is smaller at positions closer to the interior support, the convex bottom flange in compression produces a uniformly distributed radial tensile stress on the web. In parabolic haunches, where the downward slope of the bottom flange is larger at positions closer to the interior support, the concave bottom flange in compression produces a uniformly distributed radial compressive stress on the web. The magnitude of the radial stress in each case is dependent on the radius of curvature of the flange. Blodgett (1982) provides a rational approach for computing and evaluating the effect of the combined stresses on the web, which typically are not of significant concern unless the radius of curvature of the flange is unusually sharp. If the girder web is unstiffened or transversely stiffened with a stiffener spacing d_o greater than approximately $1.5D$ within a parabolic haunch adjacent to an interior support, the Engineer should consider checking the stability of the web under the effect of the radial compressive force.

At points where an inclined bottom flange becomes horizontal, the vertical component of the inclined flange force is transferred back into the web as a concentrated

6.10.1.5—Stiffness

The following stiffness properties shall be used in the analysis of flexural members:

- **For loads applied to noncomposite sections:** the stiffness properties of the steel section alone.
- **For permanent loads applied to composite sections:** the stiffness properties of the long-term composite section, assuming the concrete deck to be effective over the entire span length.
- **For transient loads applied to composite sections:** the stiffness properties of the short-term composite section, assuming the concrete deck to be effective over the entire span length.

The requirement for the modeling of girder torsional stiffness in curved and/or skewed I-girder bridges specified in Article 4.6.3.3.2 shall be satisfied for grid analyses or plate and eccentric beam analyses of steel I-girder bridges.

6.10.1.6—Flange Stresses and Member Bending Moments

For design checks where the flexural resistance is based on LTB:

- The stress, f_{bu} , shall be determined as the value of the flange compressive stress at the cross-section where $f_{bu}/R_b R_h F_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections, calculated without consideration of flange lateral bending.
- The moment, M_u , shall be determined as the value of the major-axis bending moment at the cross-section

load. This concentrated load causes additional stress in the web, and therefore, full- or partial-depth stiffening of the web must be provided at these points, except as discussed below. Full-depth stiffeners should be positively attached to both flanges and partial-depth stiffeners should be positively attached to the bottom flange. At these locations, the web is sufficient without additional stiffening if the provisions of Article D6.5.2 are satisfied for the factored vertical component of the inclined flange force using a length of bearing N equal to zero. At locations where the concentrated load is compressive and N is equal to zero, the provisions of Article D6.5.2 generally govern relative to those of Article D6.5.3; therefore, satisfaction of the provisions of Article D6.5.2 using a length of bearing N equal to zero ensures that the web is adequate without additional stiffening for locations subjected to compressive or tensile concentrated transverse loads.

C6.10.1.5

In line with common practice, it is specified that the stiffness of the steel section alone be used for noncomposite sections, although numerous field tests have shown that considerable unintended composite action occurs in such sections.

Field tests of composite continuous bridges have shown that there is considerable composite action in negative bending regions (Baldwin et al., 1978) (Roeder and Eltvik, 1985) (Yen et al., 1995). Therefore, the stiffness of the full composite section is to be used over the entire bridge length for the analysis of composite flexural members.

C6.10.1.6

For checking of the LTB resistance in cases where Article 6.10.8.2.3 is applied, the value of the stress f_{bu} is taken as the flange compressive stress at the cross-section where $f_{bu}/R_b R_h F_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections, calculated without consideration of flange lateral bending. For checking of the LTB resistance in cases where Article A6.3.3 is applied, the value of M_u is the moment at the location where $M_u/R_{pc} M_{yc}$ is maximum in the unbraced length under consideration. Articles C6.10.8.2.3a and CA6.3.3.1 discuss these aspects of the LTB resistance calculations in detail.

where $M_u/R_{pc}M_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections.

- The stress, f_t , shall be determined as the largest value of the stress due to lateral bending throughout the unbraced length in the flange under consideration.

where:

F_{yc} = specified minimum yield strength of the compression flange at the cross-section under consideration (ksi)

M_{yc} = yield moment with respect to the compression flange at the cross-section under consideration determined as specified in Article D6.2 (kip-in.)

R_b = minimum web load-shedding factor within the unbraced length under consideration including the end cross-sections, determined as specified in Article 6.10.1.10.2

R_h = hybrid factor at the cross-section under consideration determined as specified in Article 6.10.1.10.1

R_{pc} = web plastification factor for the compression flange at the cross-section under consideration determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

For design checks where the flexural resistance is based on yielding, FLB or web bend-buckling, f_{bu} , M_u , and f_t may be determined as the corresponding values at the section under consideration.

The values of f_{bu} , M_u , and f_t shall be determined based on factored loads, and shall be taken as positive in sign in all resistance equations.

Lateral bending stresses in continuously braced flanges shall be taken equal to zero. Lateral bending stresses in discretely braced flanges shall be determined by structural analysis. All discretely braced flanges shall satisfy:

$$f_t \leq 0.6F_{yf} \quad (6.10.1.6-1)$$

The flange lateral bending stress, f_t , may be determined directly from first-order elastic analysis in discretely braced compression flanges for which:

$$L_b \leq 1.1L_p \sqrt{\frac{C_b R_b}{f_{bu} / F_{yc}}} \quad (6.10.1.6-2)$$

or equivalently:

$$L_b \leq 1.1L_p \sqrt{\frac{C_b R_b}{M_u / M_{yc}}} \quad (6.10.1.6-3)$$

For a discretely braced compression flange also subject to lateral bending, the largest lateral bending stress throughout the unbraced length of the flange under consideration must be used when the resistance is based on LTB. Combined vertical and flange lateral bending is addressed in these Specifications by effectively handling the flanges as equivalent beam-columns. The use of maximum values within the unbraced length, when the resistance is governed by member stability, i.e., LTB, is consistent with established practice in the proper application of beam-column interaction equations.

Yielding, FLB, and web bend-buckling are considered as cross-section limit states. Hence, the Engineer is allowed to use coincident cross-section values of f_t and f_{bu} or M_u when checking these limit states. Generally, this approach necessitates checking of the limit states at various cross-sections along the unbraced length. When the maximum values of f_t and f_{bu} or M_u occur at different locations within the unbraced length, it is conservative to use the maximum values in a single application of the yielding and FLB equations. Flange lateral bending does not enter into the web bend-buckling resistance equations.

In lieu of a more refined analysis, Article C6.10.3.4.1 gives approximate equations for calculation of the maximum flange lateral bending moments due to eccentric concrete deck overhang loads acting on cantilever-forming brackets placed along exterior members. Determination of flange wind moments is addressed in Article 4.6.2.7. The determination of flange lateral bending moments due to the effect of discontinuous cross-frames and/or support skew is best handled by a direct structural analysis of the bridge superstructure. The determination of flange lateral bending moments due to curvature is addressed in Article 4.6.1.2.4b.

In all resistance equations, f_{bu} , M_u , and f_t are to be taken as positive in sign. However, when summing dead and live load stresses or moments to obtain the total factored major-axis stresses or moments, f_{bu} or M_u , and total factored lateral bending stresses, f_t , to apply in the equations, the signs of the individual stresses or moments

where:

- C_b = for Eq. 6.10.1.6-2, moment-gradient modifier calculated as specified in Article 6.10.8.2.3b or 6.10.8.2.3c, as applicable. For Eq. 6.10.1.6-3, moment-gradient modifier calculated as specified in Article A6.3.3.2 or A6.3.3.3, as applicable.
- f_{bu} = for unbraced lengths where Article 6.10.8.2.3 is applied, value of the flange compressive stress at the cross-section where $f_{bu}/R_b R_h F_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections, calculated without consideration of flange lateral bending (ksi)
- F_{yc} = specified minimum yield strength of the compression flange at the cross-section where $f_{bu}/R_b R_h F_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections (ksi)
- L_b = unbraced length (in.)
- L_p = for Eq. 6.10.1.6-2, limiting unbraced length given by Eq. 6.10.8.2.3a-4. For Eq. 6.10.1.6-3, limiting unbraced length given by Eq. A6.3.3.1-4 (in.)
- M_u = for unbraced lengths where Article A6.3.3 is applied, value of the major-axis bending moment at the cross-section where $M_u/R_{pc} M_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections (kip-in.)
- M_{yc} = yield moment with respect to the compression flange determined as specified in Article D6.2 at the cross-section where $M_u/R_{pc} M_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections (kip-in.)
- R_b = for Eq. 6.10.1.6-2, minimum web load-shedding factor within the unbraced length under consideration including the end cross-sections, determined as specified in Article 6.10.1.10.2. For Eq. 6.10.1.6-3, taken equal to 1.0.

If Eq. 6.10.1.6-2, or Eq. 6.10.1.6-3 as applicable, is not satisfied, second-order elastic compression flange lateral bending stresses shall be determined.

Second-order compression flange lateral bending stresses may be approximated by amplifying first-order values as follows:

$$f_e = \left(\frac{0.85}{1 - \frac{f_{bu}}{F_e}} \right) f_{e1} \geq f_{e1} \quad (6.10.1.6-4)$$

or equivalently:

must be considered. Where a dead load effect reduces the magnitude of the net force effect at the strength limit state, the minimum load factor specified in Table 3.4.1-2 and the corresponding load modifier, η , specified in Article 1.3.2.1 should be applied to that dead load effect.

The top flange may be considered continuously braced where it is encased in concrete or anchored to the deck by shear connectors satisfying the provisions of Article 6.10.10. For a continuously braced flange in tension or compression, flange lateral bending effects need not be considered. Additional lateral bending stresses are small once the concrete deck has been placed. Lateral bending stresses induced in a continuously braced flange prior to this stage need not be considered after the deck has been placed. The resistance of the composite concrete deck is generally adequate to compensate for the neglect of these initial lateral bending stresses. The Engineer should consider the noncomposite lateral bending stresses in the top flange if the flange is not continuously supported by the deck.

The provisions of Article 6.10 for handling of combined vertical and flange lateral bending are limited to I-sections that are loaded predominantly in major-axis bending. For cases in which the elastically computed flange lateral bending stress is larger than approximately $0.6F_{yf}$, the reduction in the major-axis bending resistance due to flange lateral bending tends to be greater than that determined based on these provisions. The service and strength limit state provisions of these Specifications are sufficient to ensure acceptable performance of I-girders with elastically computed f_l values somewhat larger than this limit.

Eq. 6.10.1.6-2, or equivalently Eq. 6.10.1.6-3 as applicable, gives a maximum value of L_b for which $f_l = f_{l1}$ in Eq. 6.10.1.6-4 or 6.10.1.6-5. Eq. 6.10.1.6-4, or equivalently Eq. 6.10.1.6-5 as applicable, is an approximate formula that accounts for the amplification of the first-order compression flange lateral bending stresses due to second-order effects. Eqs. 6.10.1.6-4 and 6.10.1.6-5 are established forms for estimating the maximum second-order elastic moments in braced beam-column members whose ends are restrained by other framing and tend to be

The definitions of a compact web and of a noncompact web are discussed in Article C6.10.6.2.3.

Figure C6.10.1.6-1—Second-order Elastic Lateral Deflections due to Horizontal Curvature Effects versus the Unwinding Stability Failure Mode of the Compression flange

6.10.1.7—Minimum Negative Flexure Concrete Deck Reinforcement

Wherever the longitudinal tensile stress in the concrete deck due to either the factored construction loads or Load Combination Service II in Table 3.4.1-1 exceeds ϕf_r , the cross-sectional area of the longitudinal reinforcement shall not be less than one percent of the cross-sectional area of the concrete deck. When partial-depth precast deck panels are used, the cross-sectional area of the concrete deck in the preceding requirement shall be taken as the cross-sectional area of the cast-in-place portion of the concrete deck only. ϕ shall be taken as 0.9 and f_r shall be taken as the modulus of rupture of the concrete determined as follows:

- **For normal weight concrete:** $f_r = 0.24\sqrt{f'_c}$
- **For lightweight concrete:** f_r is calculated as specified in Article 5.4.2.6,

The longitudinal stresses in the concrete deck shall be determined as specified in Article 6.10.1.1.d. The reinforcement used to satisfy this requirement shall have a specified minimum yield strength not less than 60.0 ksi; the size of the reinforcement should not exceed No. 6 bars.

Except as specified herein, the required reinforcement should be placed in two layers uniformly distributed across the deck width, and two-thirds should be placed in the top layer. The individual bars should be spaced at intervals not exceeding 12.0 in. When partial-depth precast deck panels are used, the required reinforcement should be placed in a single layer, uniformly distributed across the deck width.

Where shear connectors are omitted from the negative flexure region, all longitudinal reinforcement shall be extended into the positive flexure region beyond the additional shear connectors specified in Article 6.10.10.3 a distance not less than the development length specified in Section 5.

C6.10.1.7

The use of one percent reinforcement with a size not exceeding No. 6 bars, a yield strength greater than or equal to 60.0 ksi, and spacing at intervals not exceeding 12.0 in. is intended to control concrete deck cracking. Pertinent criteria for concrete crack control are discussed in more detail in AASHTO (1991) and in Haaijer et al. (1987).

Previously, the requirement for one percent longitudinal reinforcement was limited to negative flexure regions of continuous spans, which are often implicitly taken as the regions between points of dead load contraflexure. Under moving live loads, the deck can experience significant tensile stresses outside the points of dead load contraflexure. Placement of the concrete deck in stages can also produce negative flexure during construction in regions where the deck already has been placed, although these regions may be subjected primarily to positive flexure in the final condition. Thermal and shrinkage strains can also cause tensile stresses in the deck in regions where such stresses otherwise might not be anticipated. To address these issues, the one percent longitudinal reinforcement is to be placed wherever the tensile stress in the deck due to either the factored construction loads, including loads during the various phases of the deck placement sequence, or due to Load Combination Service II in Table 3.4.1-1, exceeds ϕf_r . By satisfying the provisions of this Article to control the crack size in regions where adequate shear connection is also provided, the concrete deck may be considered to be effective in tension for computing fatigue stress ranges, as permitted in Article 6.6.1.2.1, and in determining flexural stresses on the composite section due to Load Combination Service II, as permitted in Article 6.10.4.2.1.

Studies by Ge et al. (2021) on the design for deck stresses over partial-depth precast deck panels in negative moment regions of continuous-span girders determined that the cross-sectional area of the longitudinal reinforcement should not be less than one percent of the

cross-sectional area of the cast-in-place portion of the concrete deck.

In addition to providing one percent longitudinal deck reinforcement, nominal yielding of this reinforcement should be prevented at Load Combination Service II (Carskaddan, 1980) (AASHTO, 1991) (Grubb, 1993) to control concrete deck cracking. The use of longitudinal deck reinforcement with a specified minimum yield strength not less than 60.0 ksi may be taken to preclude nominal yielding of the longitudinal reinforcement under this load combination in the following cases:

- unshored construction where the steel section utilizes steel with a specified minimum yield strength less than or equal to 70.0 ksi in either flange, or
- shored construction where the steel section utilizes steel with a specified minimum yield strength less than or equal to 50.0 ksi in either flange.

In these cases, the effects of any nominal yielding within the longitudinal reinforcing steel are judged to be insignificant. Otherwise, the Engineer should check to ensure that nominal yielding of the longitudinal reinforcement does not occur under the applicable Service II loads. The above rules are based on Carskaddan (1980) and apply for members that are designed by the provisions of Article 6.10 or Appendix A6, as well as for members that are designed for redistribution of the pier section moments at the Service II Load Combination using the provisions of Appendix B6.

Where feasible, approximately two-thirds of the required reinforcement should be placed in the top layer. When partial-depth precast deck panels are used as deck forms, it may not be possible to place the longitudinal reinforcement in two layers. In such cases, the longitudinal reinforcement should be placed in a single layer (Ge et al., 2021).

6.10.1.8—Tension Flanges with Holes

When checking flexural members at the strength limit state or for constructibility, the following additional requirement shall be satisfied at all cross-sections containing holes in the tension flange:

$$f_t \leq 0.84 \left(\frac{A_n}{A_g} \right) F_u \leq F_y \quad (6.10.1.8-1)$$

where:

A_n = net area of the tension flange determined as specified in Article 6.8.3 (in.²)

A_g = gross area of the tension flange (in.²)

C6.10.1.8

Eq. 6.10.1.8-1 provides a limit on the maximum major-axis bending stress permitted on the gross section of the girder, neglecting the loss of area due to holes in the tension flange. This equation is used in lieu of the 15 percent rule in the AASHTO *Standard Specifications for Highway Bridges* (2002), which allows holes with an area less than or equal to 15 percent of the gross area of the flange to be neglected. For higher-strength steels, with a higher yield-to-ultimate strength ratio than Grade 36 steel, the 15 percent rule is not valid; such steels are better handled using Eq. 6.10.1.8-1. For holes larger than those typically used for connectors such as bolts, refer to Article 6.8.1.

At compact composite sections in positive flexure and at sections designed according to the optional

- f_t = stress on the gross area of the tension flange due to the factored loads calculated without consideration of flange lateral bending (ksi)
- F_u = specified minimum tensile strength of the tension flange determined as specified in Table 6.4.1-1 (ksi)

provisions of Appendix A6 with no holes in the tension flange, the nominal flexural resistance is permitted to exceed the moment at first yield at the strength limit state. Pending the results from further research, it is conservatively required that Eq. 6.10.1.8-1 also be satisfied at the strength limit state at any such cross-sections containing holes in the tension flange. It has not yet been fully documented that complete plastification of the cross-section can occur at these sections prior to fracture on the net section of the tension flange. Furthermore, the splice design provisions of Article 6.13.6.1.3 do not consider the contribution of substantial web yielding to the flexural resistance of these sections. Eq. 6.10.1.8-1 will likely prevent holes from being located in the tension flange at or near points of maximum applied moment where significant yielding of the web, beyond the localized yielding permitted in hybrid sections, may occur.

The factor 0.84 in Eq. 6.10.1.8-1 is approximately equivalent to the ratio of the resistance factor for fracture of tension members, ϕ_u , to the resistance factor for yielding of tension members, ϕ_y , specified in Article 6.5.4.2.

6.10.1.9—Web Bend-Buckling Resistance

6.10.1.9.1—Webs without Longitudinal Stiffeners

The nominal bend-buckling resistance shall be taken as:

$$F_{crw} = \frac{0.9Ek}{\left(\frac{D}{t_w}\right)^2} \quad (6.10.1.9.1-1)$$

but not to exceed the smaller of $R_h F_{yc}$ and $F_{yw}/0.7$

in which:

$$k = \text{bend-buckling coefficient}$$

$$= \frac{9}{(D_c/D)^2} \quad (6.10.1.9.1-2)$$

where:

D_c = depth of the web in compression in the elastic range (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.

D = web depth (in.)

R_h = hybrid factor specified in Article 6.10.1.10.1

When both edges of the web are in compression, k shall be taken as 7.2.

C6.10.1.9.1

In subsequent Articles, the web theoretical bend-buckling resistance is checked generally against the maximum compression-flange stress due to the factored loads, calculated without consideration of flange lateral bending. The precision associated with making a distinction between the stress in the compression flange and the maximum compressive stress in the web is not warranted. The potential use of a value of F_{crw} greater than the specified minimum yield strength of the web, F_{yw} , in hybrid sections is justified since the flange tends to restrain the longitudinal strains associated with web bend-buckling for nominal compression-flange stresses up to $R_h F_{yc}$. A stable nominally elastic compression flange constrains the longitudinal and plate bending strains in the inelastic web at the web-flange juncture (ASCE, 1968). ASCE (1968) recommends that web bend-buckling does not need to be considered in hybrid sections with F_{yc} up to 100 ksi as long as the web slenderness does not exceed $5.87\sqrt{E/F_{yc}}$. Eq. 6.10.1.9.1-1 predicts $F_{crw} = F_{yc}$ at $2D_c/t_w = 5.7\sqrt{E/F_{yc}}$. For hybrid sections with $F_{yw}/F_{yc} < 0.7$, these provisions adopt a more conservative approach than recommended by ASCE (1968) by limiting F_{crw} to the smaller of $R_h F_{yc}$ and $F_{yw}/0.7$. The flexural resistance equations of these Specifications give somewhat conservative predictions for the strengths of hybrid members without longitudinal stiffeners tested by Lew and Toprac (1968) that had D/t_w and $2D_c/t_w$ values as high as 305 and $F_{yw}/F_{yc} = 0.32$. Therefore, no additional requirements are necessary at the strength limit state for all potential values of F_{yw}/F_{yc} associated with the steels specified in Article 6.4.1.

In many experimental tests, noticeable web plate bending deformations and associated transverse displacements occur from the onset of load application due to initial web out-of-flatness. Because of the stable post-buckling behavior of the web, there is no significant change in the rate of increase of the web transverse displacements as a function of the applied loads as the theoretical web bend-buckling stress is exceeded (Basler et al., 1960). Due to unavoidable geometric imperfections, the web bend-buckling behavior is a load-deflection rather than a bifurcation problem. The theoretical web-buckling load is used in these Specifications as a simple index for controlling the web plate bending strains and transverse displacements.

For a doubly symmetric I-section without longitudinal web stiffeners, Eq. 6.10.1.9.1-2 gives $k = 36.0$, which is approximately equal to $k_{ss} + 0.8(k_{sf} - k_{ss})$, where $k_{ss} = 23.9$ and $k_{sf} = 39.6$ are the bend-buckling coefficients for simply supported and fully restrained longitudinal edge conditions, respectively (Timoshenko and Gere, 1961). For I-sections in which $D_c \neq 0.5D$, Eq. 6.10.1.9.1-2 provides a reasonable approximation of theoretical bend-buckling resistance (Ziemian, 2010) consistent with the above.

For composite sections subjected to positive flexure, these Specifications do not require the use of Eq. 6.10.1.9.1-1 after the section is in its final composite condition for webs that do not require longitudinal stiffeners based on Article 6.10.2.1.1. The section must be checked for web bend-buckling during construction while in the noncomposite condition. For loads applied at the fatigue and service limit states after the deck has hardened or is made composite, the increased compressive stresses in the web tend to be compensated for by the increase in F_{crw} resulting from the corresponding decrease in D_c . At the strength limit state, these compensating effects continue. Based on the section proportioning limits specified in Article 6.10.2 and the ductility requirement specified in Article 6.10.7.3, F_{crw} for these sections is generally close to or larger than F_{yc} at the strength limit state.

For composite sections in positive flexure in which longitudinal web stiffeners are required based on Article 6.10.2.1.1, the web slenderness requirement of Article 6.10.2.1.2 is not sufficient in general to ensure that theoretical bend-buckling of the web will not occur. Therefore, the Specifications require the calculation of R_b for these types of sections, as discussed further in Article C6.10.1.10.2.

For composite sections in negative flexure, D_c is to be computed using the section consisting of the steel girder plus the longitudinal deck reinforcement, with the one possible exception noted at the service limit state in Article D6.3.1. This approach limits the potential complications in subsequent load rating resulting from the flexural resistance being a function of D_c and D_c being taken as a function of the applied load. This approach leads to a more conservative calculation of the flexural

6.10.1.9.2—Webs with Longitudinal Stiffeners

In lieu of an alternative rational analysis, the nominal bend-buckling resistance may be determined as specified in Eq. 6.10.1.9.1-1, with the bend-buckling coefficient taken as follows:

- If $\frac{d_s}{D_c} \geq 0.4$, then:

$$k = \frac{5.17}{(d_s/D)^2} \geq \frac{9}{(D_c/D)^2} \quad (6.10.1.9.2-1)$$

- If $\frac{d_s}{D_c} < 0.4$, then:

$$k = \frac{11.64}{\left(\frac{D_c - d_s}{D}\right)^2} \quad (6.10.1.9.2-2)$$

where:

d_s = distance from the centerline of the closest plate longitudinal stiffener or from the gauge line of the closest angle longitudinal stiffener to the inner surface or leg of the compression flange element (in.)

When both edges of the web are in compression, k shall be taken as 7.2.

resistance, but the influence on the resistance is typically inconsequential.

Near points of permanent-load contraflexure, both edges of the web may be in compression when stresses in the steel and composite sections due to moments of opposite sign are accumulated. In this case, the neutral axis lies outside the web. Thus, the specification states that k be taken equal to 7.2 when both edges of the web are in compression, which is approximately equal to the theoretical bend-buckling coefficient for a web plate under uniform compression assuming fully restrained longitudinal edge conditions (Timoshenko and Gere, 1961). Such a case is relatively rare and the accumulated web compressive stresses are typically small when it occurs; however, this case may need to be considered in computer software.

C6.10.1.9.2

Eqs. 6.10.1.9.2-1 and 6.10.1.9.2-2 give an accurate approximation of the bend-buckling coefficient k for webs with a single longitudinal stiffener in any vertical location (Frank and Helwig, 1995). The resulting k depends on the location of the closest longitudinal web stiffener to the compression-flange with respect to its optimum location at $d_s/D_c = 0.4$ (Vincent, 1969) and is used to determine the bend-buckling resistance from Eq. 6.10.1.9.1-1.

Changes in flange size cause D_c to vary along the length of a girder. In a composite girder, D_c is also a function of the applied load. If the longitudinal stiffener is located a fixed distance from the compression-flange, which is normally the case, the stiffener cannot be at its optimum location throughout the girder length. In composite girders with longitudinally stiffened webs subjected to positive flexure, D_c tends to be large for noncomposite loadings during construction and therefore web bend-buckling must be checked. Furthermore, D_c can be sufficiently large for the composite girder at the service limit state such that web bend-buckling may still be a concern. Therefore, the value of D_c for checking web bend-buckling of these sections in regions of positive flexure at the service limit state is to be determined based on the accumulated flexural stresses due to the factored loads, as specified in Article D6.3.1.

For composite sections in negative flexure, D_c is to be computed in the same manner as discussed in Article C6.10.1.9.1.

Eqs. 6.10.1.9.2-1 and 6.10.1.9.2-2 and the associated optimum stiffener location assume simply supported boundary conditions at the flanges. These equations for k allow the Engineer to compute the web bend-buckling resistance for any position of the longitudinal stiffener with respect to D_c . When the distance from the closest longitudinal stiffener to the compression-flange, d_s , is less than $0.4D_c$, the stiffener is above its optimum location and web bend-buckling occurs in the panel between the stiffener and the tension flange. When d_s is greater than

$0.4D_o$, web bend-buckling occurs in the panel between the stiffener and the compression-flange. When d_s is equal to $0.4D_o$, the stiffener is at its optimum location and bend-buckling occurs in both panels. For this case, both equations yield a k value equal to 129.3 for a symmetrical girder (Dubas, 1948). Further information on locating longitudinal stiffeners on the web may be found in Article C6.10.11.3.1.

Since bend-buckling of a longitudinally stiffened web must be investigated for both noncomposite and composite stress conditions and at various locations along the girder, it is possible that the stiffener might be located at an inefficient position for a particular condition, resulting in a small bend-buckling coefficient. Because simply supported boundary conditions were assumed in the development of Eqs. 6.10.1.9.2-1 and 6.10.1.9.2-2, the computed web bend-buckling resistance for the longitudinally stiffened web may be less than that computed for a web of the same dimensions without longitudinal stiffeners where some rotational restraint from the flanges has been assumed. To prevent this anomaly, the Specifications state that the k value for a longitudinally stiffened web from Eq. 6.10.1.9.2-1 must equal or exceed a value of $9.0/(D_o/D)^2$, which is the k value for a web without longitudinal stiffeners from Eq. 6.10.1.9.1-2 computed assuming partial rotational restraint from the flanges. Note this limit only need be checked when Eq. 6.10.1.9.2-1 controls.

As discussed further in Article C6.10.1.9.1, when both edges of the web are in compression, the bend-buckling coefficient is taken equal to 7.2.

Eqs. 6.10.1.9.2-1 and 6.10.1.9.2-2 neglect the benefit of placing more than one longitudinal stiffener on the web. Therefore, they may be used conservatively for webs with multiple longitudinal stiffeners. Alternatively, the Engineer is permitted to determine F_{crw} of Eq. 6.10.1.9.1-1 or the corresponding k value for use within this equation by a direct buckling analysis of the web panel. The boundary conditions at the flanges and at the stiffener locations should be assumed as simply supported in this analysis.

6.10.1.10—Flange-Strength Reduction Factors

6.10.1.10.1—Hybrid Factor, R_h

For rolled shapes, homogenous built-up sections and built-up sections with a higher-strength steel in the web than in both flanges, R_h shall be taken as 1.0. Otherwise, in lieu of an alternative rational analysis, the hybrid factor shall be taken as:

$$R_h = \frac{12 + \beta(3\rho - \rho^3)}{12 + 2\beta} \quad (6.10.1.10.1-1)$$

in which:

C6.10.1.10.1

The R_h factor accounts for the reduced contribution of the web to the nominal flexural resistance at first yield in any flange element, due to earlier yielding of the lower-strength steel in the web of a hybrid section. As used herein, the term flange element is defined as a flange or cover plate or the longitudinal reinforcement.

Eq. 6.10.1.10.1-1 represents a condensation of the formulas for R_h in previous AASHTO Specifications and considers all possible combinations associated with different positions of the elastic neutral axis and different yield strengths of the top and bottom flange elements. The fundamental equation, originally derived for a

$$\beta = \frac{2 D_n t_w}{A_{fn}} \quad (6.10.1.10.1-2)$$

ρ = the smaller of F_{yw}/f_n and 1.0

where:

A_{fn} = sum of the flange area and the area of any cover plates on the side of the neutral axis corresponding to D_n (in.²). For composite sections in negative flexure, the area of the longitudinal reinforcement may be included in calculating A_{fn} for the top flange.

D_n = larger of the distances from the elastic neutral axis of the cross-section to the inside face of either flange (in.). For sections where the neutral axis is at the mid-depth of the web, the distance from the neutral axis to the inside face of the flange on the side of the neutral axis where yielding occurs first.

f_n = for sections where yielding occurs first in the flange, a cover plate or the longitudinal reinforcement on the side of the neutral axis corresponding to D_n , the largest of the specified minimum yield strengths of each component included in the calculation of A_{fn} (ksi). Otherwise, the largest of the elastic stresses in the flange, cover plate or longitudinal reinforcement on the side of the neutral axis corresponding to D_n at first yield on the opposite side of the neutral axis.

doubly symmetric I-section (ASCE, 1968) (Schilling, 1968) (Frost and Schilling, 1964), is adapted in these provisions to handle singly symmetric and composite sections by focusing on the side of the neutral axis where yielding occurs first. This side of the neutral axis has the most extensive web yielding prior to first yielding of any flange element. All flange elements on this side of the neutral axis are conservatively assumed to be located at the edge of the web. The equation is also adapted by assuming that the shift in the neutral axis due to the onset of web yielding is negligible. These assumptions are similar to those used in the development of a separate R_h equation for composite sections in prior AASHTO Specifications. In lieu of the approximate Eq. 6.10.1.10.1-1, the Engineer may determine R_h based on a direct iterative strain compatibility analysis. Since the computed R_h values by any approach are typically close to 1.0, the conservative assumptions made in the derivation of the simplified single noniterative Eq. 6.10.1.10.1-1 should not result in a significant economic penalty.

For hybrid longitudinally stiffened sections in negative flexure that do not satisfy Eq. 6.10.1.10.2-1, that is, for which the web load-shedding factor, R_b , is less than 1.0, Article C6.10.1.10.2 suggests the potential use of an alternative strain compatibility analysis, using an effective-width cross-section model, to perform a combined R_b and R_h calculation in cases with highly slender longitudinally stiffened webs with a large fraction of the web depth in compression. The need for separate calculation of the hybrid factor, R_h , is eliminated for such sections when this analysis is employed.

For composite sections in positive flexure, D_n may be taken conservatively as the distance from the neutral axis of the short-term composite section to the inside face of the bottom flange. This approach is strongly recommended to prevent possible complications in subsequent load rating resulting from the flexural resistance being a function of D_n and D_n being a function of the applied load.

For composite sections where the neutral axis is at the mid-depth of the web and where first yield occurs simultaneously in both flange elements, D_n should be taken as the distance to the flange element with the smaller A_{fn} .

For longitudinally stiffened sections, all longitudinal stiffeners should be included in the calculation of D_c and in the section properties associated with the calculation of f_n .

6.10.1.10.2—Web Load-Shedding Factor, R_b

When checking constructibility according to the provisions of Article 6.10.3.2, or:

- the section is composite and is in positive flexure and the web satisfies the requirement of Article 6.10.2.1.1 or 6.11.2.1.2, as applicable, or:

C6.10.1.10.2

The term R_b is a post-buckling strength reduction factor that accounts for the nonlinear variation of stresses subsequent to local bend-buckling of slender webs. This factor accounts for the reduction in the section flexural resistance caused by the shedding of compressive stresses from a slender web and the corresponding increase in the flexural stress within the compression flange.

- the web satisfies:

$$\frac{2D_c}{t_w} \leq \lambda_{rw} \quad (6.10.1.10.2-1)$$

then R_b shall be taken equal to 1.0.

Otherwise:

- in lieu of a strain compatibility analysis considering the web effective widths, for longitudinally stiffened sections in which one or more continuous longitudinal stiffeners are provided that satisfy $d_s/D_c < 0.76$:

$$R_b = 1.07 - 0.12 \frac{D_c}{D} - \frac{a_{wc}}{1200 + 300a_{wc}} \left[\frac{D}{t_w} - \lambda_{rwD} \right] \leq 1.0 \quad (6.10.1.10.2-2)$$

- for all other cases:

$$R_b = 1.0 - \frac{a_{wc}}{1200 + 300a_{wc}} \left(\frac{2D_c}{t_w} - \lambda_{rw} \right) \leq 1.0 \quad (6.10.1.10.2-3)$$

Article 6.10.1.10.2 provides two equations for R_b . Eq. 6.10.1.10.2-2 is a fit to data from Subramanian and White (2016a and 2017c) for the bend buckling strength reduction in longitudinally stiffened girders. The R_b factor given by Eq. 6.10.1.10.2-3 is based on extensive experimental and theoretical studies (Ziemian, 2010) of nonlongitudinally stiffened girders and is the more refined of two equations developed by Basler and Thurlimann (1961). Both of these equations depend on the difference between the web slenderness, expressed as D/t_w and $2D_c/t_w$ respectively, and the corresponding web slenderness limits at which the strength reduction due to bend buckling becomes significant, expressed as λ_{rwD} and λ_{rw} respectively. Both equations also depend significantly on the ratio of the area or equivalent area of two times the area of the girder web in compression to the area of the compression flange, a_{wc} . For homogeneous longitudinally stiffened girders, and for all nonlongitudinally stiffened girders, the λ_{rwD} and λ_{rw} limits correspond to the state at which the web theoretical elastic bend buckling stress is equal to the compression flange yield strength, F_{yc} . These limits are quantified by Eq. 6.10.1.10.2-6 for homogeneous longitudinally stiffened girders and by Eq. 6.10.1.10.2-5 for nonlongitudinally stiffened girders. Hybrid longitudinally stiffened girders exhibit significant strength reductions due to combined early web yielding and web bend-buckling at smaller values of the web slenderness than that corresponding to theoretical elastic bend buckling at F_{yc} (Subramanian and White, 2017d). This behavior is captured by Eq. 6.10.1.10.2-7, which sets this limit effectively at the same web slenderness as that for a nonlongitudinally stiffened girder. However, the strength reduction given by Eq. 6.10.1.10.2-2 is generally less than that given by Eq. 6.10.1.10.2-3. That is, the R_b values from Eq. 6.10.1.10.2-2 are generally larger for girders with the same $2D_c/t_w$ and a_{wc} values, due to the use of D/t_w and λ_{rwD} rather than $2D_c/t_w$ and λ_{rw} in the last term of the equation. For both hybrid longitudinally stiffened and nonlongitudinally stiffened girders, the combined effects of load shedding to the compression flange due to web bend-buckling and early web yielding are quantified by the product of R_b with the hybrid strength reduction factor, R_h , from Article 6.10.1.10.1. In all cases, the R_b factor is not applied in determining the nominal flexural resistance of the tension flange since the tension flange stress is not increased significantly by the shedding of the web compressive stresses (Basler and Thurlimann, 1961).

When computing the nominal flexural resistance of the compression flange for checking constructibility according to the provisions of Article 6.10.3.2, R_b is always to be taken equal to 1.0. This condition is ensured in these Specifications for all homogeneous slender-web sections by limiting the compression flange flexural stresses under the factored loads during construction to the elastic bend-buckling resistance of the web, F_{crw} . Hybrid girders may experience some local web buckling prior to reaching the theoretical elastic bend buckling stress, due to the early

in which:

λ_{rw} = limiting slenderness ratio for a noncompact web, expressed in terms of $2D_c/t_w$, calculated as follows:

- for longitudinally stiffened sections:

$$= \left(\frac{2D_c}{D} \right) \lambda_{rwD} \quad (6.10.1.10.2-4)$$

- for all other cases:

$$= c_{rw} \sqrt{\frac{E}{F_{yc}}} \quad (6.10.1.10.2-5)$$

λ_{rwD} = limiting slenderness ratio for a noncompact web, expressed in terms of D/t_w , calculated as follows:

- for homogeneous longitudinally stiffened sections:

$$= 0.95 \sqrt{\frac{Ek}{F_{yc}}} \quad (6.10.1.10.2-6)$$

- for hybrid longitudinally stiffened sections:

$$= \left(\frac{1}{2D_c/D} \right) 5.7 \sqrt{\frac{E}{F_{yc}}} \quad (6.10.1.10.2-7)$$

c_{rw} = edge-condition coefficient taken as:

$$c_{rw} = \left(3.1 + \frac{5.0}{a_{wc}} \right) \quad (6.10.1.10.2-8)$$

$$4.6 \leq c_{rw} \leq 5.7$$

a_{wc} = for all sections except as noted below, ratio of two times the web area in compression to the area of the compression flange

$$= \frac{2D_c t_w}{b_{fc} t_{fc}} \quad (6.10.1.10.2-9)$$

for composite longitudinally stiffened sections in positive flexure:

$$= \frac{2D_c t_w}{b_{fc} t_{fc} + b_s t_s (1 - f_{DC1} / F_{yc}) / 3n} \quad (6.10.1.10.2-10)$$

onset of yielding in the web. This condition has not been found to impact the girder performance.

For composite sections in positive flexure at the strength limit state, R_b is generally equal to or close to 1.0 for sections that satisfy the requirements of Articles 6.10.2.2 and 6.10.7.3, as long as the requirement of Article 6.10.2.1.1 is also met such that longitudinal stiffeners are not required. This is particularly true when a transformed area of the concrete deck is taken as part of the compression flange area as implemented for longitudinally stiffened sections in Eq. 6.10.1.10.2-10. Therefore, the reduction in the flexural resistance due to web bend-buckling is zero or negligible and R_b is simply taken equal to 1.0 for these sections.

For sections in positive or negative flexure with one or more longitudinal web stiffeners that satisfy Eq. 6.10.1.10.2-1, R_b is taken equal to 1.0. For homogeneous sections with these characteristics, the web slenderness, D/t_w , is at or below the value at which the theoretical elastic bend-buckling stress at the strength limit state is equal to F_{yc} given by Eq. 6.10.1.10.2-6. For a homogeneous doubly symmetric girder, i.e., $D_c = 0.5D$, with a single longitudinal stiffener located at the optimum position on the web, this limit is as follows for different grades of steel:

Table C6.10.1.10.2-1—Limiting Slenderness Ratio for $R_b = 1.0$ in a Homogeneous Longitudinally Stiffened Girder with the Stiffener at the Optimum Location and $D_c/D = 0.5$

F_{yc} (ksi)	$0.95 \sqrt{\frac{Ek}{F_{yc}}}$
36.0	300
50.0	260
70.0	220
90.0	194
100.0	184

For homogeneous singly symmetric girders with $D_c/D > 0.5$ and/or where a single longitudinal stiffener is not located at its optimum position, the limiting D/t_w from Eq. 6.10.1.10.2-6 generally will be less than the value shown in Table C6.10.1.10.2-1.

For composite sections in regions of positive flexure, the concrete deck typically contributes a large fraction of the flexural resistance as a compression flange element. For longitudinally stiffened sections of this type, Eq. 6.10.1.10.2-10 accounts for this contribution conservatively in the calculation of R_b by including a fraction of the transformed deck area based on the $3n$ section with the steel compression flange area in computing the a_{wc} term. D_c in Eq. 6.10.1.10.2-10 is to be computed as specified for composite sections in positive flexure in Article D6.3.1 and is a function of the applied loads. The relationship of the position of the longitudinal stiffener to D_c and the resulting effect on the web bend-buckling coefficient, k , is discussed further in

where:

- b_{fc} = full width of the compression flange
 b_s = effective width of the concrete deck (in.)
 d_s = distance from the centerline of the closest plate longitudinal stiffener or from the gauge line of the closest angle longitudinal stiffener to the inner surface or leg of the compression flange element (in.)
 D = web depth (in.)
 D_c = depth of the web in compression in the elastic range (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1. For longitudinally stiffened sections, all longitudinal stiffeners including any longitudinal stiffeners in the tension zone of the web, shall be included in the calculation of D_c .
 f_{DC1} = compression-flange stress at the section under consideration, calculated without consideration of flange lateral bending and caused by the factored permanent load applied before the concrete deck has hardened or is made composite (ksi)
 k = bend-buckling coefficient for webs with longitudinal stiffeners, determined as specified in Article 6.10.1.9.2
 n = modular ratio, determined as specified in Article 6.10.1.1b
 t_{fc} = thickness of the compression flange (in.)
 t_s = thickness of concrete deck (in.)
 t_w = web thickness (in.)

Articles C6.10.1.9.2 and C6.10.11.3.1. In cases where R_b is equal to 1.0 for these sections, potential difficulties during load rating associated with the dependency of the flexural resistance on D_c and the dependency of D_c on the applied loading are avoided.

Eq. 6.10.1.10.2-6 ignores the beneficial effect of placing more than one longitudinal stiffener on the web. For webs with more than one longitudinal stiffener, homogeneous girders may be proportioned for $R_b = 1.0$ if F_{crw} determined by an alternative rational analysis conducted as specified in Article C6.10.1.9.2, is greater than or equal to F_{yc} .

For nonlongitudinally stiffened composite sections in negative flexure and nonlongitudinally stiffened noncomposite sections that satisfy Eq. 6.10.1.10.2-1, R_b is also taken equal to 1.0 since the web slenderness, $2D_c/t_w$, is at or below the value given by Eq. 6.10.1.10.2-5 at which the theoretical elastic bend-buckling stress is equal to F_{yc} at the strength limit state. Eq. 6.10.1.10.2-5 also defines the slenderness limit for a noncompact web for sections with these characteristics. Nonlongitudinally stiffened webs with slenderness ratios exceeding Eq. 6.10.1.10.2-5 are termed slender. For different grades of steel, the lower and upper values of this slenderness limit are as follows:

Table C6.10.1.10.2-2—Lower and Upper Values of the Limiting Slenderness Ratio for a Noncompact Web and $R_b = 1.0$ in Girders without Web Longitudinal Stiffeners

F_{yc} (ksi)	$\lambda_{rw} = 4.6 \sqrt{\frac{E}{F_{yc}}}$	$\lambda_{rw} = 5.7 \sqrt{\frac{E}{F_{yc}}}$
36.0	130	162
50.0	111	137
70.0	94	116
90.0	82	102
100.0	78	97

The classification of webs as compact, noncompact, or slender in these Specifications applies to composite sections in negative flexure and noncomposite sections. These classifications are consistent with those in AISC (2022b). For composite sections in positive flexure, these Specifications still classify the entire cross-section as compact or noncompact based on the criteria in Article 6.10.6.2.2. The Article 6.10.6.2.2 classification includes consideration of the web slenderness as well as other cross-section characteristics.

The factor 5.7 in Eq. 6.10.1.10.2-8 is based on a bend-buckling coefficient $k = 36.0$, which is approximately equal to $k_{ss} + 0.8(k_{sf} - k_{ss})$, where $k_{ss} = 23.9$ and $k_{sf} = 39.6$ are the bend-buckling coefficients for simply supported and fully restrained longitudinal edge conditions, respectively, in webs without longitudinal stiffeners (Timoshenko and Gere, 1961). The factor 4.6 in this equation is based on idealized simply supported edge conditions. Subramanian and White (2016a) show that 4.6 is representative of the strength limit state behavior of girders with relatively large webs compared to the compression flange area, i.e., $a_{wc} > 3.33$, and 5.7 is more representative for girders with $a_{wc} < 1.92$. The related Eq. 6.10.1.9.1-1 gives the web flexural stress at the theoretical onset of web bend-buckling, whereas Eq. 6.10.1.10.2-3 quantifies the effect of the post-buckled web on the overall girder flexural resistance. Eq. 6.10.1.9.1-1 uses a constant $k = 36.0$ for doubly symmetric sections in all cases, and a constant $k = 36.0$ based on an equivalent web slenderness of $2D_c/t_w$ in all singly symmetric cases. This is a simplification recognizing the acceptable service, construction and fatigue performance of girders proportioned using this simplified estimate.

For nonlongitudinally stiffened composite sections in negative flexure and general nonlongitudinally stiffened noncomposite sections that do not satisfy Eq. 6.10.1.10.2-1, R_b is to be computed from Eq. 6.10.1.10.2-3. For composite sections in negative flexure, D_c is to be computed for the section consisting of the steel girder plus the longitudinal deck reinforcement when determining R_b for reasons discussed in Article C6.10.1.9.1. For compression flanges with cover plates, the cover plate area may be added to the flange area $b_{fc}t_{fc}$ in the denominator of Eq. 6.10.1.10.2-9.

While previous specifications have suggested that it is acceptable to substitute the actual compression-flange stress due to the factored loads, f_{bu} , calculated without consideration of flange lateral bending, for F_{yc} in the web slenderness limit equations, such a refinement is not likely to lead to a significant increase in the value of R_b . In addition, this practice does not necessarily result in improvements in the accuracy of the strength predictions (Subramanian and White, 2017c). Use of the actual flange stress to compute the flexural resistance can also lead to subsequent difficulties in load rating since the flexural

resistance then becomes a function of the applied load. Therefore, it is recommended that R_b should always be calculated based on the compression flange yield strength, F_{yc} .

The studies by Subramanian and White (2016a and 2017d) illustrate the significant contribution of a continuous longitudinal stiffener to the flexural resistance of sections in negative flexure that are loaded into the web post-buckling range at the strength limit state. These studies found that, for girders that do not satisfy Eq. 6.10.1.10.2-1, the most accurate prediction of the web post-buckling, or R_b effects, in longitudinally stiffened homogeneous girders, and the most accurate prediction of the combined web yielding and web post-buckling, or $R_b R_h$ effects, in longitudinally stiffened hybrid sections in negative flexure is accomplished by calculating the ultimate moment capacity from an iterative strain compatibility analysis considering specified effective widths of the web panels. For homogeneous longitudinally stiffened girders, this type of strain compatibility analysis gives acceptable estimates of test simulation resistances that range from only 4 percent smaller to 11 percent larger than the R_b values obtained from Eq. 6.10.1.10.2-2. For hybrid longitudinally stiffened girders, the strain compatibility analysis gives acceptable estimates of test simulation resistances that range from 7 percent smaller to 17 percent larger than the $R_b R_h$ values obtained from Eqs. 6.10.1.10.1-1 and 6.10.1.10.2-2. This iterative strain compatibility analysis is recommended for longitudinally stiffened girders where additional calculated capacities are needed, and where D_c/D is greater than 0.5 and $(D/t_w - \lambda_{rwD})$ is larger than 110. The additional calculated capacity from the strain compatibility analysis model tends to be marginal to none in other cases. The recommended cross-section models for performing the strain compatibility analysis for homogeneous and hybrid longitudinally stiffened girders are given in Subramanian and White (2017c and 2017d). Subramanian and White (2016a; 2016b; 2017a; 2017b; 2017c) demonstrate the applicability of the recommended strain compatibility analysis models with the corresponding Specification provisions for the LTB, FLB, and tension-flange yielding limit states in straight and curved girders.

Eq. 6.10.1.10.2-2 and the recommended strain compatibility analysis models assume that the longitudinal stiffener is continuous at the ends of the web panel under consideration. This may be achieved by continuing the longitudinal stiffener across the transverse stiffener locations on the side of the web opposite from the transverse stiffeners, or by positively attaching the longitudinal stiffener on each side of the transverse stiffener at both ends of the panel when the stiffeners are on the same side of the web. The longitudinally stiffened web panel must be an interior panel, adjacent to at least one additional panel into which the longitudinal stiffener is continued, for the longitudinal stiffening to be considered effective for calculation of the post-buckling

flexural resistance at the strength limit state. The contribution of the longitudinal stiffener to the post-buckling flexural resistance of the girder at the strength limit state is to be neglected when the panel has longitudinal stiffeners that are not continuous; that is, Eq. 6.10.1.10.2-3 must be used to compute R_b and Eq. 6.10.1.10.2-5 must be used to compute λ_{crw} . Provision of a longitudinal stiffener that is discontinued at one end of the web panel is still deemed to satisfy the Article 6.10.2.1.2 requirements. The contribution of any longitudinal stiffeners located in the tension zone of the web, or with $d_s/D_c > 0.76$, is ignored in Eq. 6.10.1.10.2-2 and in the recommended cross-section strain compatibility analysis models.

The requirements for proportioning of longitudinal stiffeners in Article 6.10.11.3 ensure the development of the elastic web bend-buckling resistance specified in Article 6.10.1.9. Elastic bend buckling of longitudinally stiffened webs is theoretically prevented up through the service limit state in these Specifications, but is permitted at the strength limit state. The minimum stiffener proportioning requirements do not ensure that a horizontal line of near zero lateral deflection will be maintained for the subsequent post-bend-buckling response of the web, particularly at web slenderness values significantly larger than 200 (Subramanian and White, 2017c). However, satisfaction of the minimum stiffener proportioning requirements allows R_b to be taken as 1.0 up through the service limit state. While it may be beneficial to increase the stiffener rigidity to some extent from the minimum requirements in order to increase the post-buckling strength, the increase in strength is minor and there are generally diminishing returns as the stiffener size is increased beyond twice the minimum proportioning requirements (Subramanian and White, 2016b).

6.10.2—Cross-Section Proportion Limits

6.10.2.1—Web Proportions

6.10.2.1.1—Webs without Longitudinal Stiffeners

C6.10.2.1.1

Webs shall be proportioned such that:

$$\frac{D}{t_w} \leq 150 \quad (6.10.2.1.1-1)$$

Eq. 6.10.2.1.1-1 is a practical upper limit on the slenderness of webs without longitudinal stiffeners expressed in terms of the web depth, D . This equation allows for simple proportioning of the web in preliminary design. Furthermore, satisfaction of Eq. 6.10.2.1.1-1 allows web bend-buckling to be disregarded in the design of composite sections in positive flexure, as discussed further in Article C6.10.1.9.1. The limit in Eq. 6.10.2.1.1-1 is valid for sections with specified minimum yield strengths up to and including 100.0 ksi designed according to these Specifications.

The vertical flange buckling limit-state equations in AISC (2022b), which are based in large part on ASCE (1968), are not considered in these Specifications.

These equations specify a limit on the web slenderness to prevent theoretical elastic buckling of the web as a column subjected to a radial transverse compression due to the curvature of the flanges. For girders that satisfy Eq. 6.10.2.1.1-1, these equations do not govern the web slenderness unless F_{yc} is greater than 85.0 ksi. Furthermore, tests conducted by Lew and Toprac (1968), Cooper (1967), and others, in which the final failure mode involved vertical flange buckling, or a folding of the compression-flange vertically into the web, indicate that the influence of this failure mode on the predicted girder flexural resistances is small. This is the case even for girders with parameters that significantly violate the vertical flange buckling limit-state equations.

6.10.2.1.2—Webs with Longitudinal Stiffeners

C6.10.2.1.2

Webs shall be proportioned such that:

$$\frac{D}{t_w} \leq 300 \quad (6.10.2.1.2-1)$$

Eq. 6.10.2.1.2-1 is a practical upper limit on the slenderness of webs with longitudinal stiffeners expressed in terms of the web depth, D . This limit allows for simple proportioning of the web for preliminary design. The limit in Eq. 6.10.2.1.2-1 is valid for sections with specified minimum yield strengths up to and including 100.0 ksi designed according to these Specifications.

Cooper (1967) discusses the conservatism of vertical flange buckling limit-state equations and the justification for not considering this limit state in longitudinally stiffened I-girders. Tests by Cooper (1967), Owen et al. (1970) and others have demonstrated that the flexural resistance is not adversely affected by final failure modes involving vertical flange buckling, even for longitudinally stiffened girders that significantly exceed the limit of Eq. 6.10.2.1.2-1. In all cases involving a vertical flange buckling type of failure, extensive flexural yielding of the compression flange preceded the failure. However, webs that have larger D/t_w values than specified by Eq. 6.10.2.1.2-1 are relatively inefficient, are likely to be more susceptible to distortion-induced fatigue, and are more susceptible to the limit states of web crippling and web yielding of Article D6.5.

6.10.2.2—Flange Proportions

C6.10.2.2

Compression and tension flanges shall be proportioned such that:

$$\frac{b_f}{2t_f} \leq 12.0, \quad (6.10.2.2-1)$$

$$b_f \geq D / 6, \quad (6.10.2.2-2)$$

Eq. 6.10.2.2-1 is a practical upper limit to ensure the flange will not distort excessively when welded to the web.

White and Barth (1998) observe that the cross-section aspect ratio D/b_f is a significant parameter affecting the strength and moment-rotation characteristics of I-sections. Eq. 6.10.2.2-2 limits this ratio to a maximum value of 6. Experimental test data are limited for sections with very narrow flanges. A significant number of the limited tests that have been conducted have indicated relatively low nominal flexural and shear resistances relative to the values determined using these specifications. Limiting this ratio to a

maximum value of six for both the compression and tension flanges ensures that stiffened interior web panels, with the section along the entire panel proportioned to satisfy Eq. 6.10.9.3.2-1, can develop post-buckling shear resistance due to tension-field action (White et al., 2004). Eq. 6.10.2.2-2 provides a lower limit on the flange width. In most practical cases, a wider flange will be required, particularly for horizontally curved girders.

To help ensure that individual girder field sections will be stable and easier to handle for lifting, erection, and shipping without the need for special stiffening trusses or falsework, the following guideline should also be satisfied:

$$b_{tfs} \geq \frac{L_{fs}}{85} \quad (\text{C6.10.2.2-1})$$

where:

b_{fs} = smallest top-flange width within the unsplined individual girder field section under consideration (in.)

L_{fs} = length of the unspliced individual girder field section under consideration (in.)

Eq. C6.10.2.2-1 should be used during the design, in conjunction with the flange proportioning limits specified in Article 6.10.2.2, to establish a minimum required top-flange width for each individual unspliced girder field section. It should be emphasized that Eq. C6.10.2.2-1 is provided merely as a guideline and is not an absolute requirement. It is also not intended that the Engineer attempt to anticipate how the individual field sections may eventually be assembled or spliced together and/or stabilized or supported for shipping or erection in the application of the preceding guideline; the guideline is only to be applied to individual unspliced girder field sections for design. The stability of steel girders for shipping and erection either as individual shipping pieces or after being spliced together to form larger pieces should be considered the responsibility of the Contractor (NHI, 2015a).

Eq. 6.10.2.2-3 ensures that some restraint will be provided by the flanges against web shear buckling, and also that the boundary conditions assumed at the web-flange juncture in the web bend-buckling and compression FLB formulations within these Specifications are sufficiently accurate. The ratio of the web area to the compression-flange area is always less than or equal to 5.45 for members that satisfy Eqs. 6.10.2.2-2 and 6.10.2.2-3. Therefore, the AISC (2022b) limit of 10 on this ratio is not required.

An I-section with a ratio of I_{xx}/I_{yy} outside the limits specified in Eq. 6.10.2.2-4 is more like a T-section with the shear center located at the intersection of the larger flange and the web. Eq. 6.10.2.2-4 ensures more efficient flange proportions and prevents the use of sections that may be particularly difficult to handle during

$$t_f \geq 1.1 t_w, \quad (6.10.2.2-3)$$

and:

$$0.1 \leq \frac{I_{yc}}{I_{yf}} \leq 10 \quad (6.10.2.2-4)$$

where:

I_{yc} = moment of inertia of the compression flange of the steel section about the vertical axis in the plane of the web (in.⁴)

I_{yt} = moment of inertia of the tension flange of the steel section about the vertical axis in the plane of the web (in.⁴)

construction. Also, Eq. 6.10.2.2-4 ensures the validity of the equations for $C_b > 1$ in cases involving moment gradients. Furthermore, these limits tend to prevent the use of extremely monosymmetric sections for which the larger of the yield moments, M_{yc} or M_{yt} , may be greater than the plastic moment, M_p . If the flanges are composed of plates of equal thickness, these limits are equivalent to $b_{fc} \geq 0.46b_{ft}$ and $b_{ft} \leq 2.15b_{fc}$.

6.10.3—Constructibility

6.10.3.1—General

The provisions of Article 2.5.3 shall apply. In addition to providing adequate strength, nominal yielding or reliance on post-buckling resistance shall not be permitted for main load-carrying members during critical stages of construction, except for yielding of the web in hybrid sections. This shall be accomplished by satisfying the requirements of Articles 6.10.3.2 and 6.10.3.3 at each critical construction stage. For sections in positive flexure that are composite in the final condition, but are noncomposite during construction, the provisions of Article 6.10.3.4 shall apply. For investigating the constructibility of flexural members, all loads shall be factored as specified in Article 3.4.2. For the calculation of deflections, the load factors shall be taken as 1.0.

Potential uplift at bearings shall be investigated at each critical construction stage.

Webs without bearing stiffeners at locations subjected to concentrated loads not transmitted through a deck or deck system shall satisfy the provisions of Article D6.5.

If there are holes in the tension flange at the section under consideration, the tension flange shall also satisfy the requirement specified in Article 6.10.1.8.

Pretensioned high-strength bolted slip-critical connections, as defined in Article 6.13.2.1.1, either in or to flexural members shall be proportioned to prevent slip under the factored loads during the deck placement. The Strength I load combination specified in Article 3.4.2.1 and the provisions of Article 6.13.2.8 shall apply for the investigation of connection slip.

6.10.3.2—Flexure

6.10.3.2.1—Discretely Braced Flanges in Compression

For critical stages of construction, each of the following requirements shall be satisfied. For sections with slender webs, Eq. 6.10.3.2.1-1 shall not be checked when f_t is equal to zero. For sections with compact or noncompact webs, Eq. 6.10.3.2.1-3 shall not be checked.

$$f_{bu} + f_t \leq \phi_f R_h F_{yc}, \quad (6.10.3.2.1-1)$$

$$f_{bu} + \frac{1}{3}f_t \leq \phi_f F_{nc}, \quad (6.10.3.2.1-2)$$

C6.10.3.1

If uplift is indicated at any critical stage of construction, temporary load may be placed to prevent lift-off. The magnitude and position of any required temporary load should be provided in the contract documents.

Factored forces in pretensioned high-strength bolted slip-critical connections either in or to flexural members are limited to the slip resistance of the connection during the deck placement to ensure that the correct geometry of the structure is maintained.

C6.10.3.2.1

A distinction is made between discretely and continuously braced compression and tension flanges because for a continuously braced flange, flange lateral bending need not be considered.

This Article gives constructibility requirements for discretely braced compression flanges, expressed by Eqs. 6.10.3.2.1-1, 6.10.3.2.1-2, and 6.10.3.2.1-3 in terms of the combined factored vertical and flange lateral bending stresses during construction. In making these checks, the stresses, f_{bu} and f_t must be determined according to the procedures specified in Article 6.10.1.6.

to express the resistance in terms of stress for direct application in Eq. 6.10.3.2.1-2. In some cases, the calculated resistance will exceed F_{yc} since Appendix A6 accounts in general for flexural resistances greater than the yield moment resistance, M_{yc} or M_{yt} . However, Eq. 6.10.3.2.1-1 will control in these cases, thus ensuring that the combined factored stress in the flange will not exceed F_{yc} times the hybrid factor during construction.

The rationale for calculation of S_{xc} , as defined in this Article for use in determining F_{nc} for sections with noncompact or compact webs, is discussed in Article CA6.1.1.

For sections that are composite in the final condition, but are noncomposite during construction, different values of the hybrid factor, R_h , must be calculated for checks in which the member is noncomposite and for checks in which the member is composite.

Because the flange stress is limited to the web bend-buckling stress according to Eq. 6.10.3.2.1-3, the R_b factor is always to be taken equal to 1.0 in computing the nominal flexural resistance of the compression flange for constructibility.

Should the web bend-buckling resistance be exceeded for the construction condition, the Engineer has several options to consider. These options include providing a larger compression flange or a smaller tension flange to decrease the depth of the web in compression, adjusting the deck placement sequence to reduce the compressive stress in the web, or providing a thicker web. Should these options not prove to be practical or cost-effective, a longitudinal web stiffener can be provided. As specified in Article 6.10.11.3.1, the longitudinal stiffener must be located vertically on the web to satisfy Eq. 6.10.3.2.1-3 for the construction condition, Eq. 6.10.4.2.2-4 at the service limit state and all the appropriate design requirements at the strength limit state. Further discussions of procedures for locating a longitudinal stiffener are provided in Article C6.10.11.3.1.

6.10.3.2.2—Discretely Braced Flanges in Tension

For critical stages of construction, the following requirement shall be satisfied:

$$f_{bu} + f_t \leq \phi_f R_h F_{yt} \quad (6.10.3.2.2-1)$$

6.10.3.2.3—Continuously Braced Flanges in Tension or Compression

For critical stages of construction, the following requirement shall be satisfied:

$$f_{bu} \leq \phi_f R_h F_{yf} \quad (6.10.3.2.3-1)$$

C6.10.3.2.2

For a discretely braced flange in tension, Eq. 6.10.3.2.2-1 ensures that the stress in the flange will not exceed the specified minimum yield strength of the flange times the hybrid factor during construction under the combination of the major-axis bending and lateral bending stresses due to the factored loads.

C6.10.3.2.3

This Article assumes that a continuously braced flange in compression is not subject to local or the LTB. Article C6.10.1.6 states the conditions for which a flange may be considered to be continuously braced. By encasing the flange in concrete or by attaching the flange to the concrete deck by shear connectors that satisfy the requirements of Article 6.10.10, one side of the flange is

For noncomposite sections with slender webs, flanges in compression shall also satisfy Eq. 6.10.3.2.1-3.

6.10.3.2.4—Concrete Deck

The longitudinal tensile stress in a composite concrete deck due to the factored loads shall not exceed ϕf_r during critical stages of construction, unless longitudinal reinforcement is provided according to the provisions of Article 6.10.1.7. The concrete stress shall be determined as specified in Article 6.10.1.1.d. ϕ and f_r shall be taken as specified in Article 6.10.1.7.

6.10.3.3—Shear

Webs shall satisfy the following requirement during critical stages of construction:

$$V_u \leq \phi_v V_{cr} \quad (6.10.3.3-1)$$

where:

- ϕ_v = resistance factor for shear specified in Article 6.5.4.2
- V_u = shear in the web acting on the noncomposite section under consideration due to the factored load for constructibility specified in Article 3.4.2.1 (kip)
- V_{cr} = shear yielding or shear buckling resistance determined from Eq. 6.10.9.3.3-1 (kip)

6.10.3.4—Deck Placement

6.10.3.4.1—General

Sections in positive flexure that are composite in the final condition, but are noncomposite during construction, shall be investigated for flexure according

effectively prevented from local buckling, or both sides of the flange must buckle in the direction away from the concrete deck. Therefore, highly restrained boundary conditions are provided in effect at the web-flange juncture. Also, the flange lateral bending deflections, required to obtain a significant reduction in strength associated with FLB, are effectively prevented by the concrete deck. Therefore, neither flange local nor the LTB need to be checked for compression flanges that satisfy the proportioning limits of Article 6.10.2.2 and are continuously braced according to the conditions stated in Article C6.10.1.6.

C6.10.3.2.4

This Article is intended to address primarily the situation when the concrete deck is placed in a span adjacent to a span where the concrete has already been placed. Negative moment in the adjacent span causes tensile stresses in the previously placed concrete. Also, if long placements are made such that a negative flexure region is included in the first placement, it is possible that the concrete in this region will be stressed in tension during the remainder of the deck placement, which may lead to early cracking of the deck. When the longitudinal tensile stress in the deck exceeds the factored modulus of rupture of the concrete, longitudinal reinforcement is to be provided according to the provisions of Article 6.10.1.7 to control the cracking. Stresses in the concrete deck are to be computed using the short-term modular ratio, n , per Article 6.10.1.1.d.

C6.10.3.3

The web is to be investigated for the sum of the factored permanent loads and factored construction loads applied to the noncomposite section during construction. The nominal shear resistance for this check is limited to the shear yielding or shear buckling resistance per Eq. 6.10.9.3.3-1. The use of tension-field action per Eq. 6.10.9.3.2-2 is not permitted under these loads during construction. Use of tension-field action is permitted after the deck has hardened or is made composite, if the section along the entire panel is proportioned to satisfy Eq. 6.10.9.3.2-1.

C6.10.3.4.1

The entire concrete deck may not be placed in one stage; thus, parts of the girders may become composite in sequential stages. If certain deck placement sequences are

to the provisions of Article 6.10.3.2 during the various stages of the deck placement.

Geometric properties, bracing lengths, and stresses used in calculating the nominal flexural resistance shall be for the steel section only. Changes in load, stiffness, and bracing during the various stages of the deck placement shall be considered.

The effects of forces from deck overhang brackets acting on the fascia girders shall be considered.

followed, the temporary moments induced in the girders during the deck placement can be considerably higher than the final noncomposite dead load moments after the sequential placement is complete.

Sequentially staged concrete placement can also result in significant tensile strains in the previously placed deck in adjacent spans. When cracking is predicted, longitudinal deck reinforcement as specified in Article 6.10.3.2.4 is required to control the cracking. Temporary dead load deflections during sequential deck placement can also be different from final noncomposite dead load deflections. If the differences are deemed significant, this should be considered when establishing girder cambers that are subsequently considered in setting screed requirements for construction, as specified in Article 6.7.2. These constructibility concerns apply to deck replacement as well as initial construction.

During construction of steel-girder bridges, concrete deck overhang loads are typically supported by cantilever-forming brackets typically placed at 3.0- to 4.0-ft spacings along the exterior members. The eccentricity of the deck weight and other loads acting on the overhang brackets creates applied torsional moments on the exterior members. As a result, the following issues must be considered in the design of the exterior members:

- The applied torsional moments bend the exterior girder top flanges outward. The resulting flange lateral bending stresses tend to be largest at the brace points at one or both ends of the unbraced length. The lateral bending stress in the top flange is tensile at the brace points on the side of the flange opposite from the brackets. These lateral bending stresses should be considered in the design of the flanges.
- The horizontal components of the reactions on the cantilever-forming brackets are often transmitted directly onto the exterior girder web. The girder web may exhibit significant plate bending deformations due to these loads. The effect of these deformations on the vertical deflections at the outside edge of the deck should be considered. The effect of the reactions from the brackets on the cross-frame forces should also be considered.
- Excessive deformation of the web or top flange may lead to excessive deflection of the bracket supports causing the deck finish to be problematic.

Where practical, forming brackets should be carried to the intersection of the bottom flange and the web. Alternatively, the brackets may bear on the girder webs if means are provided to ensure that the web is not damaged. The provisions of Article 6.10.3.2 allow for the consideration of the flange lateral bending stresses in the design of the flanges. In the absence of a more refined analysis, either of the following equations may be used to

estimate the maximum flange lateral bending moments due to the eccentric loadings depending on how the lateral load is assumed applied to the top flange:

$$M_{\ell} = \frac{F_{\ell} L_b^2}{12} \quad (\text{C6.10.3.4.1-1})$$

where:

M_{ℓ} = lateral bending moment in the flanges due to the eccentric loadings from the forming brackets (kip-in.)

F_{ℓ} = statically equivalent uniformly distributed lateral force from the brackets due to the factored loads (kip/in.)

L_b = unbraced length (in.)

$$M_{\ell} = \frac{P_{\ell} L_b}{8} \quad (\text{C6.10.3.4.1-2})$$

where:

P_{ℓ} = statically equivalent concentrated lateral bracket force placed at the middle of the unbraced length (kip)

Eqs. C6.10.3.4.1-1 and C6.10.3.4.1-2 are both based on the assumption of interior unbraced lengths in which the flange is continuous with adjacent unbraced lengths, as well as equal adjacent unbraced lengths such that due to approximate symmetry boundary conditions, the ends of the unbraced length are effectively torsionally fixed. The Engineer should consider other more appropriate idealizations when these assumptions do not approximate the actual conditions.

Construction dead loads, such as those acting on the deck overhangs, are often applied to the noncomposite section and removed when the bridge has become composite. Typically, the major-axis bending moments due to these loads are small relative to other design loads. However, the Engineer may find it desirable in some cases to consider the effect of these moments, particularly in computing deflections for cambers. The lateral bending moments due to overhang loads not applied through the shear center of the girder are often more critical. Refined analysis of the noncomposite bridge for these loads provides more accurate lateral moments and may identify any rotation of the overhang that could potentially affect the elevation of the screed when finishing the deck.

The magnitude and application of the overhang loads assumed in the design should be shown in the contract documents.

6.10.3.4.2—Global Displacement Amplification in Narrow I-Girder Bridge Units

The provisions of this Article shall apply to spans of straight I-girder bridge units with three or fewer girders, interconnected by cross-frames or diaphragms, that also meet both of the following conditions in their noncomposite condition during the deck placement operation:

- the unit is not braced by other structural units and/or by external bracing within the span; and
- the unit does not contain any flange-level lateral bracing or lateral bracing from a hardened composite deck within the span.

Considering all of the girders across the width of the unit within the span under consideration, the sum of the largest total factored girder moments during the deck placement within the span under consideration should not exceed 70 percent of the elastic global LTB resistance of the span acting as a system. The elastic global LTB resistance of the span acting as a system, M_{gs} , may be calculated as follows:

$$M_{gs} = C_{bs} \frac{\pi^2 w_g E}{L^2} \sqrt{I_{eff} I_x} \quad (6.10.3.4.2-1)$$

in which:

C_{bs} = system moment-gradient modifier
 = 1.1 for simply supported units
 = 2.0 for continuous-span units

- For doubly symmetric girders:

$$I_{eff} = I_y \quad (6.10.3.4.2-2)$$

- For singly symmetric girders:

$$I_{eff} = I_{yc} + \left(\frac{t}{c}\right) I_{yt} \quad (6.10.3.4.2-3)$$

where:

c = distance from the centroid of the noncomposite steel section under consideration to the centroid of the compression flange (in.). The distance shall be taken as positive.

I_x = noncomposite moment of inertia about the horizontal centroidal axis of a single girder within the span under consideration (in.⁴)

I_{yc}, I_{yt} = moments of inertia of the compression and tension flange, respectively, about the vertical centroidal axis of a single girder within the span under consideration (in.⁴)

C6.10.3.4.2

The recommendations in this Article are intended to avoid excessive amplification of the lateral and vertical displacements of narrow straight I-girder bridge units during the deck placement operation before the concrete deck has hardened. The global buckling mode in this case refers to buckling of the bridge unit as a structural unit, and not buckling of the girders between intermediate braces. Limiting the sum of the largest total factored girder moments across the width of the unit within the span under consideration to 70 percent of the elastic global buckling resistance of the span acting as a system theoretically limits the amplification under the corresponding nominal loads to a maximum value of approximately 2.0 (Han and Helwig, 2020).

Eq. 6.10.3.4.2-1 (Yura et al., 2008) provides one method of estimating the elastic global LTB resistance of a given straight I-girder bridge span under noncomposite loading conditions. The system moment-gradient modifier, C_{bs} , in Eq. 6.10.3.4.2-1 accounts for the beneficial effect of the moment-gradient within the span on the elastic global LTB resistance of the span acting as a system, which is particularly significant for continuous-span units (Han and Helwig, 2020). A C_{bs} value of 1.1 applies to simply supported units, and should also be applied if investigating continuous-span units that are in a partially erected condition. A C_{bs} value of 2.0 applies to fully erected continuous-span units. Two-girder units are particularly susceptible to excessive global lateral-torsional amplification during the deck placement; however, units with large span/width ratios having up to three girders also may be susceptible to significant global amplification in some cases. Other methods, such as an eigenvalue buckling analysis or a global second-order load-deflection analysis, may also be used to determine the response of the system. Once a concrete deck is acting compositely with the steel girders, a given span of a bridge unit is practically always stable as an overall system; Eq. 6.10.3.4.2-1 is not intended for application to I-girder bridge spans in their composite condition. Eq. 6.10.3.4.2-1 is also not applicable to I-girder bridge units with more than three girders, which are typically not susceptible to excessive global lateral-torsional amplification during the deck placement.

Eq. 6.10.3.4.2-1 was derived assuming prismatic girders and that all girder cross-sections in the unit are the same. For cases where the girders are nonprismatic, it is recommended herein that I_x , I_{yc} and I_{yt} , as applicable, be computed by replacing each nonprismatic girder in the span with a prismatic girder with effective section properties calculated using the nonlinear length weighted average approach specified for Method B in Article D6.6.3 in calculating the elastic global LTB resistance from Eq. 6.10.3.4.2-1. For cases where the girder cross-sections vary across the width of the unit, the smallest value of I_x , I_{yc} , I_{yt} , as applicable, of the girder cross-sections

I_y	=	noncomposite moment of inertia about the vertical centroidal axis of a single girder within the span under consideration (in. ⁴)
L	=	length of the span under consideration (in.)
t	=	distance from the centroid of the noncomposite steel section under consideration to the centroid of the tension flange (in.). The distance shall be taken as positive.
w_g	=	girder spacing for a two-girder system or the distance between the two exterior girders of the unit for a three-girder system (in.)

Should the sum of the largest total factored girder moments across the width of the unit within the span under consideration exceed 70 percent of M_{gs} , the following alternatives may be considered:

- The addition of flange-level lateral bracing adjacent to the supports of the span may be considered as discussed in Article 6.7.5.2;
- The unit may be revised to increase the system stiffness; or
- The amplified girder second-order displacements of the span during the deck placement may be evaluated to verify that they are within tolerances permitted by the Owner.

within the span should conservatively be used. Also, in cases where the girder spacing is less than the girder depth, it is recommended that the more general elastic global LTB equation provided in Yura et al. (2008) be used, as Eq. 6.10.3.4.2-1 becomes more conservative in this case. Yura et al. (2008) further indicate the adjustments that need to be made to the more general buckling equation for singly symmetric girders and for three-girder systems.

Large global torsional rotations signified by large differential vertical deflections between the girders and also large lateral deflections, as determined from a first-order analysis, are indicative of the potential for significant second-order global amplification. Situations exhibiting potentially significant global second-order amplification include phased construction involving narrow unsupported units with only two or three girders and possibly unevenly applied deck weight. One suggested method of increasing the global buckling resistance in such cases is to consider the addition of flange-level lateral bracing to the system. Yura et al. (2008) suggest adjustments to be made when estimating the elastic global LTB resistance of the system where a partial top-flange lateral bracing system is present at the ends of the span, along with some associated bracing design recommendations.

The elastic global buckling resistance should only be used as a general indicator of the susceptibility of horizontally curved I-girder systems to second-order amplification under noncomposite loading conditions. Narrow horizontally curved I-girder bridge units that meet both of the conditions stated in this Article in their noncomposite condition during the deck placement may be subject to significant second-order amplification and should instead be analyzed using a global second-order load-deflection analysis to evaluate the behavior. As an alternative, the addition of flange-level lateral bracing adjacent to the supports of the span may be considered as discussed in Article 6.7.5.2, or the unit can be braced to other structural units or by external bracing within the span.

6.10.3.5—Dead Load Deflections

The provisions of Article 6.7.2 shall apply, as applicable.

C6.10.3.5

If staged construction is specified, the sequence of load application should be recognized in determining the camber and stresses.

6.10.4—Service Limit State

6.10.4.1—Elastic Deformations

The provisions of Article 2.5.2.6 shall apply, as applicable.

C6.10.4.1

The provisions of Article 2.5.2.6 contain optional live load deflection criteria and criteria for span-to-depth ratios. In the absence of depth restrictions, the span-to-depth ratios should be used to establish a reasonable minimum web depth for the design.

6.10.4.2.1—General

The following methods may be used to calculate stresses in structural steel at the Service II limit state:

- For members with shear connectors provided throughout their entire length that also satisfy the provisions of Article 6.10.1.7, flexural stresses in the structural steel caused by Service II loads applied to the composite section may be computed using the short-term or long-term composite section, as appropriate. The concrete deck may be assumed to be effective for both positive and negative flexure, provided that the maximum longitudinal tensile stresses in the concrete deck at the section under consideration caused by the Service II loads are smaller than $2f_r$, where f_r is the modulus of rupture of the concrete specified in Article 6.10.1.7.
- For sections that are composite for negative flexure with maximum longitudinal tensile stresses in the concrete deck greater than or equal to $2f_r$, the flexural stresses in the structural steel caused by Service II loads shall be computed using the section consisting of the steel section and the longitudinal reinforcement within the effective width of the concrete deck.
- For sections that are noncomposite for negative flexure, the properties of the steel section alone shall be used for calculation of the flexural stresses in the structural steel.

The longitudinal stresses in the concrete deck shall be determined as specified in Article 6.10.1.1.1d.

6.10.4.2.2—Flexure

Flanges shall satisfy the following requirements:

- For the top steel flange of composite sections:

$$f_f \leq 0.95 R_h F_{yf} \quad (6.10.4.2.2-1)$$

- For the bottom steel flange of composite sections:

$$f_f + \frac{f_\ell}{2} \leq 0.95 R_h F_{yf} \quad (6.10.4.2.2-2)$$

- For both steel flanges of noncomposite sections:

$$f_f + \frac{f_\ell}{2} \leq 0.80 R_h F_{yf} \quad (6.10.4.2.2-3)$$

C6.10.4.2.1

These provisions are intended to apply to the design live load specified in Article 3.6.1.1. If this criterion were to be applied to a design permit load, a reduction in the load factor for live load should be considered.

Article 6.10.1.7 requires that one percent longitudinal deck reinforcement be placed wherever the tensile stress in the concrete deck due to either factored construction loads or due to Load Combination Service II exceeds the factored modulus of rupture of the concrete. By controlling the crack size in regions where adequate shear connection is also provided, the concrete deck may be considered effective in tension for computing flexural stresses on the composite section due to Load Combination Service II.

The cracking behavior and the partial participation of the physically cracked slab in transferring forces in tension is very complex. Article 6.10.4.2.1 provides specific guidance that the concrete slab may be assumed to be uncracked when the maximum longitudinal concrete tensile stress is smaller than $2f_r$. This limit between the use of an uncracked or cracked section for calculation of flexural stresses in the structural steel is similar to a limit suggested in CEN (2004) beyond which the effects of concrete cracking should be considered.

C6.10.4.2.2

Eqs. 6.10.4.2.2-1 through 6.10.4.2.2-3 are intended to prevent objectionable permanent deflections due to expected severe traffic loadings that would impair rideability. For homogeneous sections with zero flange lateral bending, they correspond to the overload check in the AASHTO *Standard Specifications for Highway Bridges* (2002) and are based on successful past practice. Their development is described in Vincent (1969). A resistance factor is not applied in these equations because the specified limits are serviceability criteria for which the resistance factor is 1.0.

Eqs. 6.10.4.2.2-1 through 6.10.4.2.2-3 address the increase in flange stresses caused by early web yielding in hybrid sections by including the hybrid factor R_h .

For continuous-span members in which noncomposite sections are utilized in negative flexure regions only, it is recommended that Eqs. 6.10.4.2.2-1

where:

- f_f = flange stress at the section under consideration due to the Service II loads calculated without consideration of flange lateral bending (ksi)
- f_l = flange lateral bending stress at the section under consideration due to the Service II loads determined as specified in Article 6.10.1.6 (ksi)
- R_h = hybrid factor determined as specified in Article 6.10.1.10.1. For hybrid sections in which f_f in both flanges does not exceed the specified minimum yield strength of the web, the hybrid factor shall be taken equal to 1.0.

For continuous-span flexural members in straight I-girder bridges that satisfy the requirements of Article B6.2, a calculated percentage of the negative moment due to the Service II loads at the pier section under consideration may be redistributed using the procedures of either Article B6.3 or B6.6.

For compact composite sections in positive flexure utilized in shored construction, the longitudinal compressive stress in the concrete deck due to the Service II loads, determined as specified in Article 6.10.1.1.1d, shall not exceed $0.6f'_c$.

Except for composite sections in positive flexure in which the web satisfies the requirement of Article 6.10.2.1.1, all sections shall also satisfy the following requirement:

$$f_c \leq F_{crw} \quad (6.10.4.2.2-4)$$

where:

- f_c = compression-flange stress at the section under consideration due to the Service II loads calculated without consideration of flange lateral bending (ksi)
- F_{crw} = nominal bend-buckling resistance for webs with or without longitudinal stiffeners, as applicable, determined as specified in Article 6.10.1.9.2 (ksi)

and 6.10.4.2.2-2, as applicable, be applied in those regions.

Under the load combinations specified in Table 3.4.1-1, Eqs. 6.10.4.2.2-1 through 6.10.4.2.2-3, as applicable, do not control and need not be checked for the following sections:

- Composite sections in negative flexure for which the nominal flexural resistance under the Strength load combinations is determined according to the provisions of Article 6.10.8;
- Noncomposite sections with $f_l = 0$ and for which the nominal flexural resistance under the Strength load combinations is determined according to the provisions of Article 6.10.8;
- Noncompact composite sections in positive flexure.

However, Eq. 6.10.4.2.2-4 must still be checked for these sections where applicable.

The 1/2 factor in Eqs. 6.10.4.2.2-2 and 6.10.4.2.2-3 comes from Schilling (1996) and Yoo and Davidson (1997). Eqs. 6.10.4.2.2-2 and 6.10.4.2.2-3 with a limit of F_{yf} on the right-hand side are a close approximation to rigorous yield interaction equations for the load level corresponding to the onset of yielding at the web-flange juncture, including the effect of flange tip yielding that occurs prior to this stage, but not considering flange residual stress effects. If the flanges are nominally elastic at the web-flange juncture and the elastically computed flange lateral bending stresses are limited as required by Eq. 6.10.1.6-1, the permanent deflections will be small. The $0.95R_h$ and $0.80R_h$ factors are included on the right-hand side of Eqs. 6.10.4.2.2-2 and 6.10.4.2.2-3 to provide some additional conservatism for control of permanent deformations when the flange lateral bending is significant. The sign of f_f and f_l should always be taken as positive in Eqs. 6.10.4.2.2-2 and 6.10.4.2.2-3. However, when summing dead and live load stresses to obtain the total factored major-axis and lateral bending stresses, f_f and f_l , to apply in the equations, the signs of the individual stresses must be considered.

f_l is not included in Eq. 6.10.4.2.2-1 because the top flange is continuously braced by the concrete deck. For continuously braced top flanges of noncomposite sections, the f_l term in Eq. 6.10.4.2.2-3 may be taken equal to zero.

Lateral bending in the bottom flange is only a consideration at the service limit state for all horizontally curved I-girder bridges and for straight I-girder bridges with discontinuous cross-frame or diaphragm lines in conjunction with skews exceeding 20 degrees. Wind load and deck overhang effects are not considered at the service limit state.

Localized yielding in negative-flexural sections at interior piers results in redistribution of the elastic moments. For continuous-span flexural members in

straight I-girder bridges that satisfy the provisions of Article B6.2, the procedures of either Article B6.3 or B6.6 may be used to calculate the redistribution moments at the service limit state. These procedures represent an improvement on the former ten-percent redistribution rule. When the redistribution moments are calculated according to these procedures, Eqs. 6.10.4.2.2-1 through 6.10.4.2.2-3, as applicable, need not be checked within the regions extending from the pier section under consideration to the nearest flange transition or point of permanent-load contraflexure, whichever is closest, in each adjacent span. Eq. 6.10.4.2.2-4 must still be considered within these regions using the elastic moments prior to redistribution. At all locations outside of these regions, Eqs. 6.10.4.2.2-1 through 6.10.4.2.2-4, as applicable, must be satisfied after redistribution. Research has not yet been conducted to extend the provisions of Appendix B6 to kinked (chorded) continuous or horizontally curved steel I-girder bridges.

For compact composite sections utilized in shored construction, the longitudinal stresses in the concrete deck are limited to $0.6f'_c$ to ensure linear behavior of the concrete. In unshored construction, the concrete stress near first yielding of either steel flange is generally significantly less than f'_c thereby eliminating the need to check the concrete stress in this case.

With the exception of composite sections in positive flexure in which the web satisfies the requirement of Article 6.10.2.1.1 such that longitudinal stiffeners are not required, and web bend-buckling effects are negligible, web bend-buckling of all sections must be checked under the Service II Load Combination according to Eq. 6.10.4.2.2-4. Article C6.10.1.9.1 explains why web bend-buckling does not need to be checked for the above exception. Options to consider should the web bend-buckling resistance be exceeded are similar to those discussed for the construction condition at the end of Article C6.10.3.2.1, except of course for adjusting the deck placement sequence.

If the concrete deck is assumed effective in tension in regions of negative flexure, as permitted at the service limit state for composite sections satisfying the requirements specified in Article 6.10.4.2.1, more than half of the web may be in compression thus increasing the susceptibility to web bend-buckling. As specified in Article D6.3.1, for composite sections in negative flexure, the appropriate value of D_c to be used at the service limit state depends on whether or not the concrete deck is assumed effective in tension. For noncomposite sections, D_c of the steel section alone should always be used.

6.10.5—Fatigue and Fracture Limit State**6.10.5.1—Fatigue**

Details shall be investigated for fatigue as specified in Article 6.6.1. The applicable Fatigue load combination specified in Table 3.4.1-1 and the fatigue live load specified in Article 3.6.1.4 shall apply.

For horizontally curved I-girder bridges, the fatigue stress range due to major-axis bending plus lateral bending shall be investigated.

The provisions for fatigue in shear connectors specified in Article 6.10.10.1.2 shall apply.

6.10.5.2—Fracture

Fracture toughness requirements specified in the contract documents shall be in conformance with the provisions of Article 6.6.2.1.

6.10.5.3—Special Fatigue Requirement for Webs

For the purposes of this Article, the factored fatigue load shall be determined using the Fatigue I load combination specified in Table 3.4.1-1, with the fatigue live load taken as specified in Article 3.6.1.4.

Interior panels of webs with transverse stiffeners, with or without longitudinal stiffeners, shall satisfy the following requirement:

$$V_u \leq V_{cr} \quad (6.10.5.3-1)$$

where:

- V_u = shear in the web at the section under consideration due to the unfactored permanent load plus the factored fatigue load (kip)
- V_{cr} = shear-yielding or shear buckling resistance determined from Eq. 6.10.9.3.3-1 (kip)

C6.10.5.1

In horizontally curved I-girder bridges, the base metal adjacent to butt welds and welded attachments on discretely braced flanges subject to a net applied tensile stress must be checked for the fatigue stress range due to major-axis bending, plus flange lateral bending, at the critical transverse location on the flange. Examples of welded attachments for which this requirement applies include transverse stiffeners and gusset plates receiving lateral bracing members. The base metal adjacent to flange-to-web welds need only be checked for the stress range due to major-axis bending since the welds are located near the center of the flange. Flange lateral bending need not be considered for details attached to continuously braced flanges.

C6.10.5.3

If Eq. 6.10.5.3-1 is satisfied, significant elastic flexing of the web due to shear is not expected to occur, and the member is assumed able to sustain an infinite number of smaller loadings without fatigue cracking due to this effect.

This provision is included here, rather than in Article 6.6, because it involves a check of the maximum web shear buckling stress instead of a check of the stress ranges caused by cyclic loading.

The live load stress due to the passage of the specified fatigue live load for this check is that of the heaviest truck expected to cross the bridge in 75 years.

The check for bend-buckling of webs given in AASHTO (1998) due to the load combination specified in this Article is not included in these Specifications. For all sections, except for composite sections in positive flexure in which the web satisfies Article 6.10.2.1.1, a web bend-buckling check is required under the Service II Load Combination according to the provisions of Article 6.10.4.2.2. As discussed further in Article C6.10.1.9.1, web bend-buckling of composite sections in positive flexure is not a concern at any limit state after the section is in its final composite condition for sections with webs that satisfy Article 6.10.2.1.1. For all other sections, the web bend-buckling check under the Service II loads will control over a similar check under the load combination specified in this Article. For composite sections in positive flexure with webs that do not satisfy Article 6.10.2.1.1, the smaller value of F_{crw} resulting from the larger value of D_c at the fatigue limit

state tends to be compensated for by the lower web compressive stress due to the load combination specified in this Article. Web bend-buckling of these sections is also checked under the construction condition according to Eq. 6.10.3.2.1-3.

The shear in unstiffened webs is already limited to either the shear yielding or shear buckling resistance at the strength limit state according to the provisions of Article 6.10.9.2. The shear in end panels of stiffened webs is also limited to the shear yielding or shear buckling resistance at the strength limit state according to the provisions of Article 6.10.9.3.3. Consequently, the requirement in this Article need not be checked for unstiffened webs or the end panels of stiffened webs.

6.10.6—Strength Limit State

6.10.6.1—General

For the purposes of this Article, the applicable strength load combinations specified in Table 3.4.1-1 shall apply.

C6.10.6.1

At the strength limit state, Article 6.10.6 directs the Engineer to the appropriate Articles for the design of composite or noncomposite I-sections in regions of positive or negative flexure.

For sections in which the flexural resistance is expressed in terms of stress, the elastically computed flange stress is strictly not an estimate of the actual flange stress because of limited partial yielding within the cross-section due to the combination of applied load effects with initial residual stresses and various other incidental stress contributions not included within the design analysis calculations. The effects of partial yielding within the cross-section on the distribution of internal forces within the system prior to reaching the maximum resistances as defined in these Specifications are minor and may be neglected in the calculation of the applied stresses and/or moments.

The use of stresses is considered to be more appropriate in members within which the maximum resistance is always less than or equal to the yield moment M_y in major-axis bending. This is due to the nature of the different types of loadings that contribute to the member flexural stresses: noncomposite, long-term composite and short-term composite. The combined effects of the loadings on these different states of the member cross-section are better handled by working with flange stresses rather than moments. Bridge engineers typically are also more accustomed to working with stresses rather than moments. Therefore, although the provisions can be written equivalently in terms of bending moment, the provisions of Article 6.10 are written in terms of stress whenever the maximum potential resistance in terms of f_{bu} is less than or equal to F_y .

Conversely, for members in which the resistance is potentially greater than M_y , significant yielding within the cross-section makes the handling of the capacities in terms of stress awkward. Although the provisions that are written in terms of moment can be written equivalently in terms of elastic stress quantities, the corresponding elastic

6.10.6.2—Flexure*6.10.6.2.1—General*

If there are holes in the tension flange at the section under consideration, the tension flange shall satisfy the requirement specified in Article 6.10.1.8.

6.10.6.2.2—Composite Sections in Positive Flexure

Composite sections in kinked (chorded) continuous or horizontally curved steel-girder bridges shall be considered as noncompact sections and shall satisfy the requirements of Article 6.10.7.2.

Composite sections in straight bridges that satisfy the following requirements and are without holes in the tension flange shall qualify as compact composite sections:

- The specified minimum yield strengths of the flanges do not exceed 70.0 ksi,
- The web satisfies the requirement of Article 6.10.2.1.1, and
- The section satisfies the web slenderness limit:

$$\frac{2D_{cp}}{t_w} \leq 3.76 \sqrt{\frac{E}{F_{yc}}} \quad (6.10.6.2.2-1)$$

where:

D_{cp} = depth of the web in compression at the plastic moment determined as specified in Article D6.3.2 (in.)

Compact sections shall satisfy the requirements of Article 6.10.7.1. Otherwise, the section shall be considered noncompact and shall satisfy the requirements of Article 6.10.7.2.

Compact and noncompact sections shall satisfy the ductility requirement specified in Article 6.10.7.3.

C6.10.6.2.1

The provisions of Article 6.10.1.8 prevent the nominal flexural resistance of sections with holes in the tension flange from exceeding the moment at first yield.

C6.10.6.2.2

The nominal flexural resistance of composite sections in positive flexure in straight bridges satisfying specific steel grade, web slenderness, and ductility requirements and without holes in the tension flange may exceed the moment at first yield according to the provisions of Article 6.10.7. The nominal flexural resistance of these sections, termed compact sections, is therefore more appropriately expressed in terms of moment. For composite sections in positive flexure in straight bridges not satisfying one or more of these requirements, or for composite sections in positive flexure in horizontally curved bridges, termed noncompact sections, the nominal flexural resistance is not permitted to exceed the moment at first yield. The nominal flexural resistance in these cases is therefore more appropriately expressed in terms of the elastically computed flange stress.

Composite sections in positive flexure in straight bridges with flange yield strengths greater than 70.0 ksi or with webs that do not satisfy Article 6.10.2.1.1 are to be designed at the strength limit state as noncompact sections as specified in Article 6.10.7.2. For concrete compressive strengths typically employed for deck construction, the use of larger steel yield strengths may result in significant nonlinearity and potential crushing of the deck concrete prior to reaching the flexural resistance specified for compact sections in Article 6.10.7.1. Longitudinal stiffeners generally must be provided in sections with webs that do not satisfy Article 6.10.2.1.1. Since composite longitudinally stiffened sections tend to be deeper and used in longer spans with corresponding larger noncomposite dead load stresses, they tend to have D_c/t_w values that would preclude the development of substantial inelastic flexural strains within the web prior to bend-buckling at moment levels close to $R_h M_p$. Therefore, although the depth of the web in compression typically reduces as plastic strains associated with moments larger than $R_h M_y$ are incurred, and D_{cp} may indeed satisfy Eq. 6.10.6.2.2-1 at the plastic moment resistance, sufficient test data do not exist to support the design of these types of sections for M_p . Furthermore, because of the relative size of the steel section to the concrete deck typical for these types of sections, M_p often is not substantially larger than $R_h M_y$. Due to these factors, composite sections in positive flexure in which the web does not satisfy Article 6.10.2.1.1 are categorized as noncompact sections. Composite sections in positive flexure in kinked (chorded) continuous or horizontally curved steel bridges are also to be designed

- The flanges satisfy the following ratio:

$$\frac{I_{yc}}{I_{yt}} \geq 0.3 \quad (6.10.6.2.3-2)$$

in which:

λ_{rw} = limiting slenderness ratio for a noncompact web

$$= c_{rw} \sqrt{\frac{E}{F_{yc}}} \quad (6.10.6.2.3-3)$$

c_{rw} = edge-condition coefficient, taken as:

$$c_{rw} = \left(3.1 + \frac{5.0}{a_{wc}} \right) \quad (6.10.6.2.3-4)$$

$$4.6 \leq c_{rw} \leq 5.7$$

a_{wc} = ratio of two times the web area in compression to the area of the compression flange

$$= \frac{2 D_c t_w}{b_{fc} t_{fc}} \quad (6.10.6.2.3-5)$$

where:

D_c = depth of the web in compression in the elastic range (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.

I_{yc} = moment of inertia of the compression flange of the steel section about the vertical axis in the plane of the web (in.⁴)

I_{yt} = moment of inertia of the tension flange of the steel section about the vertical axis in the plane of the web (in.⁴)

Otherwise, the section shall be proportioned according to provisions specified in Article 6.10.8.

For continuous-span flexural members in straight bridges that satisfy the requirements of Article B6.2, a calculated percentage of the negative moments due to the factored loads at the pier section under consideration may be redistributed using the procedures of either Article B6.4 or B6.6.

to somewhat conservative determination of the nominal flexural resistance than would be obtained using Appendix A6.

For composite sections in negative flexure or noncomposite sections in straight bridges not satisfying one or more of these requirements, or for these sections in horizontally curved bridges, the provisions of Article 6.10.8 must be used.

The provisions of Article 6.10.1.8 prevent the nominal flexural resistance of sections with holes in the tension flange from exceeding the moment at first yield as permitted in Appendix A6.

Research has not yet been conducted to extend the provisions of Appendix A6 either to sections in kinked (chorded) continuous or horizontally curved steel bridges or to bridges with supports skewed more than 20 degrees from normal. Severely skewed bridges with contiguous cross-frames have significant transverse stiffness and thus already have large cross-frame forces in the elastic range. As interior-pier sections yield and begin to lose stiffness and shed their load, the forces in the adjacent cross-frames will increase. There is currently no established procedure to predict the resulting increase in the forces without performing a refined nonlinear analysis. With discontinuous cross-frames, significant lateral flange bending effects can occur. The resulting lateral bending moments and stresses are amplified in the bottom compression flange adjacent to the pier as the flange deflects laterally. There is currently no means to accurately predict these amplification effects as the flange is also yielding. Skewed supports also result in twisting of the girders, which is not recognized in plastic design theory. The relative vertical deflections of the girders create eccentricities that are also not recognized in the theory. Thus, until further research is done to examine these effects in greater detail, a conservative approach has been taken in the specification.

Eq. 6.10.6.2.3-1 defines the slenderness limit for a noncompact web. A web with a slenderness ratio exceeding this limit is termed slender. For noncompact webs, theoretical web bend-buckling does not occur for elastic stress values, computed according to beam theory, smaller than the limit of the flexural resistance. Sections with slender webs rely upon the significant web post bend-buckling resistance under Strength Load Combinations. Specific values for the noncompact web slenderness limit for different grades of steel are listed in Table C6.10.1.10.2-2.

A compact web is one that satisfies the slenderness limit given by Eq. A6.2.1-1. Sections with compact webs and $I_{yc}/I_{yt} \geq 0.3$ are able to develop their full plastic moment capacity M_p provided that other steel grade, ductility, flange slenderness and/or lateral bracing requirements are satisfied. The web slenderness limit given by Eq. A6.2.1-1 is significantly smaller than the limit shown in Table C6.10.1.10.2-2. It is generally satisfied by rolled

I-shapes, but typically not by the most efficient built-up section proportions.

The flange yield stress, F_{yc} , is more relevant to the web buckling behavior and its influence on the flexural resistance than F_{yw} . For a section that has a web proportioned at the noncompact limit, a stable nominally elastic compression flange tends to constrain a lower-strength hybrid web at stress levels less than or equal to $R_h F_{yc}$. For a section that has a compact web, the inelastic strains associated with development of the plastic flexural resistance are more closely related to the flange rather than the web yield strength.

The majority of steel bridge I-sections utilize either slender webs or noncompact webs that approach the slenderness limit of Eq. 6.10.6.2.3-1 represented by the values listed in Table C6.10.1.10.2-2. For these sections, the simpler and more streamlined provisions of Article 6.10.8 are the most appropriate for determining the nominal flexural resistance of composite sections in negative flexure and noncomposite sections. These provisions may also be applied to sections with compact webs or to sections with noncompact webs that are nearly compact, but at the expense of some economy. Such sections are typically used in bridges with shorter spans. The potential loss in economy increases with decreasing web slenderness. The Engineer should give strong consideration to utilizing the provisions of Appendix A6 to compute the nominal flexural resistance of these sections in straight bridges, in particular, sections with compact webs.

Eq. 6.10.6.2.3-2 is specified to guard against extremely monosymmetric noncomposite I-sections, in which analytical studies indicate a significant loss in the influence of the St. Venant torsional rigidity GJ on the LTB resistance due to cross-section distortion. The influence of web distortion on the LTB resistance is larger for such members. If the flanges are of equal thickness, this limit is equivalent to $b_{fc} \geq 0.67b_{ff}$.

Yielding in negative-flexural sections at interior piers at the strength limit state results in redistribution of the elastic moments. For continuous-span flexural members in straight bridges that satisfy the provisions of Article B6.2, the procedures of either Article B6.4 or B6.6 may be used to calculate redistribution moments at the strength limit state. These provisions replace the former ten-percent redistribution allowance and provide a more rational approach for calculating the percentage redistribution from interior-pier sections. When the redistribution moments are calculated according to these procedures, the flexural resistances at the strength limit state within the unbraced lengths immediately adjacent to interior-pier sections satisfying the requirements of Article B6.2 need not be checked. At all other locations, the provisions of Articles 6.10.7, 6.10.8.1 or A6.1, as applicable, must be satisfied after redistribution. The provisions of Article B6.2 are often satisfied by compact-flange unstiffened or transversely stiffened pier sections that are otherwise designed by Article 6.10.8 or Appendix A6 using $C_b = 1.0$.

Research has not yet been conducted to extend the provisions of Appendix B6 to kinked (chorded) continuous or horizontally curved steel bridges.

6.10.6.3—Shear

The provisions of Article 6.10.9 shall apply.

6.10.6.4—Shear Connectors

The provisions of Article 6.10.10.4 shall apply.

6.10.7—Flexural Resistance—Composite Sections in Positive Flexure

6.10.7.1—Compact Sections

6.10.7.1.1—General

At the strength limit state, the section shall satisfy:

$$M_u + \frac{1}{3} f_e S_{xt} \leq \phi_f M_n \quad (6.10.7.1.1-1)$$

where:

- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- f_e = flange lateral bending stress, determined as specified in Article 6.10.1.6 (ksi)
- M_n = nominal flexural resistance of the section determined as specified in Article 6.10.7.1.2 (kip-in.)
- M_u = bending moment about the major axis of the cross-section, determined as specified in Article 6.10.1.6 (kip-in.)
- M_{yt} = yield moment with respect to the tension flange, determined as specified in Article D6.2 (kip-in.)
- S_{xt} = elastic section modulus about the major axis of the section to the tension flange, taken as M_{yt}/F_{yt} (in.³)

C6.10.7.1.1

For composite sections in positive flexure, lateral bending does not need to be considered in the compression-flange at the strength limit state because the flange is continuously supported by the concrete deck.

Eq. 6.10.7.1.1-1 is an interaction equation that addresses the influence of lateral bending within the tension flange, represented by the elastically computed flange lateral bending stress, f_e , combined with the major-axis bending moment, M_u . This equation is similar to the subsequent Eqs. 6.10.7.2.1-2 and 6.10.8.1.2-1, the basis of which is explained in Article C6.10.8.1.2. However, these other equations are expressed in an elastically computed stress format, and the resistance term on their right-hand side is generally equal to $\phi_f R_h F_{yt}$. Eq. 6.10.7.1.1-1 is expressed in a bending moment format, but alternatively can be considered in a stress format by dividing both sides of the equation by the elastic section modulus, S_{xt} .

The term M_n on the right-hand side of Eq. 6.10.7.1.1-1 is generally greater than the yield moment capacity, M_{yt} . Therefore, the corresponding resistance, written in the format of an elastically computed stress, is generally greater than F_{yt} . These Specifications use a moment format for all resistance equations which, if written in terms of an elastically computed stress, can potentially assume resistance values greater than the specified minimum yield strength of the steel. In these types of sections, the major-axis bending moment is physically a more meaningful quantity than the corresponding elastically computed bending stress.

Eq. 6.10.7.1.1-1 gives a reasonably accurate but conservative representation of the results from an elastic-plastic section analysis in which a fraction of the width from the tips of the tension flange is deducted to accommodate flange lateral bending. The rationale for calculation of S_{xt} , as defined in this Article for use in Eq. 6.10.7.1.1-1, is discussed in Article CA6.1.1.

6.10.7.1.2—Nominal Flexural Resistance

The nominal flexural resistance of the section shall be taken as:

If $D_p \leq 0.1 D_t$, then:

$$M_n = M_p \quad (6.10.7.1.2-1)$$

Otherwise:

$$M_n = M_p \left(1.07 - 0.7 \frac{D_p}{D_t} \right) \quad (6.10.7.1.2-2)$$

where:

D_p = distance from the top of the concrete deck to the neutral axis of the composite section at the plastic moment (in.)

D_t = total depth of the composite section (in.)

M_p = plastic moment of the composite section determined as specified in Article D6.1 (kip-in.)

In a continuous span, the nominal flexural resistance of the section shall satisfy:

$$M_n \leq 1.3 R_h M_y \quad (6.10.7.1.2-3)$$

where:

M_n = nominal flexural resistance determined from Eq. 6.10.7.1.2-1 or 6.10.7.1.2-2, as applicable (kip-in.)

M_y = yield moment determined as specified in Article D6.2 (kip-in.)

R_h = hybrid factor determined as specified in Article 6.10.1.10.1

unless:

- the span under consideration and all adjacent interior-pier sections satisfy the requirements of Article B6.2,

and:

- the appropriate value of θ_{RL} from Article B6.6.2 exceeds 0.009 radians at all adjacent interior-pier sections,

in which case the nominal flexural resistance of the section is not subject to the limitation of Eq. 6.10.7.1.2-3.

C6.10.7.1.2

Eq. 6.10.7.1.2-2 implements the philosophy introduced by Wittry (1993) that an additional margin of safety should be applied to the theoretical nominal flexural resistance of compact composite sections in positive flexure when the depth of the plastic neutral axis below the top of the deck, D_p , exceeds a certain value. This additional margin of safety, which increases approximately as a linear function of D_p/D_t , is intended to protect the concrete deck from premature crushing, thereby ensuring adequate ductility of the composite section. Sections with D_p/D_t less than or equal to 0.1 can reach as a minimum the plastic moment, M_p , of the composite section without any ductility concerns.

Eq. 6.10.7.1.2-2 gives results that depend only on the plastic moment resistance M_p and on the ratio D_p/D_t , as also suggested in Yakel and Azizinamini (2005). The equation implements the above philosophy justified by Wittry (1993). Eq. 6.10.7.1.2-2 is somewhat restrictive for sections with small values of M_p/M_y , such as sections with hybrid webs, a relatively small deck area and a high-strength tension flange. It is somewhat less restrictive for sections with large values of M_p/M_y . Wittry (1993) considered various experimental test results and performed a large number of parametric cross-section analyses. The smallest experimental or theoretical resistance of all the cross-sections considered in this research and in other subsequent studies is $0.96M_p$. Eq. 6.10.7.1.2-2 is based on the target additional margin of safety of 1.28 specified by Wittry at the maximum allowed value of D_p combined with an assumed theoretical resistance of $0.96M_p$ at this limit. At the maximum allowed value of D_p specified by Eq. 6.10.7.3-1, the resulting nominal design flexural resistance is $0.78M_p$.

The limit of $D_p < 0.1D_t$ for the use of Eq. 6.10.7.1.2-1 is obtained by use of a single implicit β value of 0.75 in the comparable equations from AASHTO (1998). AASHTO (1998) specifies $\beta = 0.7$ for $F_y = 50$ and 70.0 ksi and $\beta = 0.9$ for $F_y = 36.0$ ksi. The value of $\beta = 0.75$ is justifiable for all cases based on the scatter in strain-hardening data. The derived β values are sensitive to the assumed strain-hardening characteristics.

The shape factor, M_p/M_y , for composite sections in positive flexure can be somewhat larger than 1.5 in certain cases. Therefore, a considerable amount of yielding and resulting inelastic curvature is required to reach M_p in these situations. This yielding reduces the effective stiffness of the positive flexural section. In continuous spans, the reduction in stiffness can shift moment from the positive to the negative-flexural regions. If the interior-pier sections in these regions do not have additional capacity to sustain these larger moments and are not designed to have ductile moment-rotation characteristics according to the provisions of Appendix B6, the shedding of moment to these sections could result in incremental collapse under repeated live load applications. Therefore, for cases where the span or

either of the adjacent interior-pier sections do not satisfy the provisions of Article B6.2, or where the appropriate value of θ_{RL} from Article B6.6.2 at either adjacent pier section is less than or equal to 0.009 radians, the positive flexural sections must satisfy Eq. 6.10.7.1.2-3.

It is possible to satisfy the above concerns by ensuring that the pier section flexural resistances are not exceeded if the positive flexural section moments above $R_h M_y$ are redistributed and combined with the concurrent negative moments at the pier sections determined from an elastic analysis. This approach is termed the Refined Method in AASHTO (1998). However, concurrent moments are not typically tracked in the analysis and so this method is not included in these Specifications.

Eq. 6.10.7.1.2-3 is provided to limit the amount of additional moment allowed above $R_h M_y$ at composite sections in positive flexure to 30 percent of $R_h M_y$ in continuous spans where the span or either of the adjacent pier sections do not satisfy the requirements of Article B6.2. The $1.3R_h M_y$ limit is the same as the limit specified for the Approximate Method in AASHTO (1998). The nominal flexural resistance determined from Eq. 6.10.7.1.2-3 is not to exceed the resistance determined from either Eq. 6.10.7.1.2-1 or 6.10.7.1.2-2, as applicable, to ensure adequate strength and ductility of the composite section. In cases where D_p/D_t is relatively large and M_p/M_y is relatively small, Eq. 6.10.7.1.2-2 may govern relative to Eq. 6.10.7.1.2-3. However, for most practical cases, Eq. 6.10.7.1.2-3 will control.

Interior-pier sections satisfying the requirements of Article B6.2 and for which the appropriate value of θ_{RL} from Article B6.6.2 exceeds 0.009 radians have sufficient ductility and robustness such that the redistribution of moments caused by partial yielding within the positive flexural regions is inconsequential. The value of 0.009 radians is taken as an upper bound for the potential increase in the inelastic rotations at the interior-pier sections due to positive-moment yielding. Thus, the nominal flexural resistance of positive flexural sections in continuous spans that meet these requirements is not limited due to the effect of potential moment shifting. These restrictions are often satisfied by compact-flange unstiffened or transversely stiffened pier sections designed by Article 6.10.8 or Appendix A6 using $C_b = 1.0$. All current ASTM A6/A6M rolled I-shapes satisfying Eqs. B6.2.1-3, B6.2.2-1, and B6.2.4-1 meet these restrictions. All built-up sections satisfying Article B6.2 that also either have $D/b_{fc} < 3.14$ or satisfy the additional requirements of Article B6.5.1 meet these restrictions.

The Engineer is not required to redistribute moments from the pier sections in order to utilize the additional resistance in positive flexure, but only to satisfy the stated restrictions from Appendix B6 that ensure significant ductility and robustness of the adjacent pier sections. Redistribution of the pier moments is permitted in these cases, if desired, according to the provisions of Appendix B6.

Assuming the fatigue and fracture limit state does not control, under the load combinations specified in Table 3.4.1-1 and in the absence of flange lateral bending, the permanent deflection service limit state criterion given by Eq. 6.10.4.2.2-2 will often govern the design of the bottom flange of compact composite sections in positive flexure wherever the nominal flexural resistance at the strength limit state is based on either Eq. 6.10.7.1.2-1, 6.10.7.1.2-2, or 6.10.7.1.2-3. Thus, it is prudent and expedient to initially design these types of sections to satisfy this permanent deflection service limit state criterion and then to subsequently check the nominal flexural resistance at the strength limit state according to the applicable Eq. 6.10.7.1.2-1, 6.10.7.1.2-2, or 6.10.7.1.2-3.

6.10.7.2—Noncompact Sections

6.10.7.2.1—General

At the strength limit state, the compression flange shall satisfy:

$$f_{bu} \leq \phi_f F_{nc} \quad (6.10.7.2.1-1)$$

where:

- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- f_{bu} = flange stress calculated without consideration of flange lateral bending determined as specified in Article 6.10.1.6 (ksi)
- F_{nc} = nominal flexural resistance of the compression flange determined as specified in Article 6.10.7.2.2 (ksi)

The tension flange shall satisfy:

$$f_{bu} + \frac{1}{3} f_\ell \leq \phi_f F_{nt} \quad (6.10.7.2.1-2)$$

where:

- f_ℓ = flange lateral bending stress determined as specified in Article 6.10.1.6 (ksi)
- F_{nt} = nominal flexural resistance of the tension flange determined as specified in Article 6.10.7.2.2 (ksi)

The maximum longitudinal compressive stress in the concrete deck at the strength limit state, determined as specified in Article 6.10.1.1.1d, shall not exceed $0.6f'_c$.

C6.10.7.2.1

For noncompact sections, the compression flange must satisfy Eq. 6.10.7.2.1-1 and the tension flange must satisfy Eq. 6.10.7.2.1-2 at the strength limit state. The basis for Eq. 6.10.7.2.1-2 is explained in Article C6.10.8.1.2. For composite sections in positive flexure, lateral bending does not need to be considered in the compression flange at the strength limit state because the flange is continuously supported by the concrete deck.

For noncompact sections, the longitudinal stress in the concrete deck is limited to $0.6f'_c$ to ensure linear behavior of the concrete, which is assumed in the calculation of the steel flange stresses. This condition is unlikely to govern except in cases involving: (1) shored construction, or unshored construction where the noncomposite steel dead load stresses are low, combined with (2) geometries causing the neutral axis of the short-term and long-term composite section to be significantly below the bottom of the concrete deck.

6.10.7.2.2—Nominal Flexural Resistance

The nominal flexural resistance of the compression flange shall be taken as:

$$F_{nc} = R_b R_h F_{yc} \quad (6.10.7.2.2-1)$$

where:

R_b = web load-shedding factor determined as specified in Article 6.10.1.10.2

R_h = hybrid factor determined as specified in Article 6.10.1.10.1

The nominal flexural resistance of the tension flange shall be taken as:

$$F_{nt} = R_h F_{yt} \quad (6.10.7.2.2-2)$$

6.10.7.3—Ductility Requirement

Compact and noncompact sections shall satisfy:

$$D_p \leq 0.42 D_t \quad (6.10.7.3-1)$$

where:

D_p = distance from the top of the concrete deck to the neutral axis of the composite section at the plastic moment (in.)

D_t = total depth of the composite section (in.)

6.10.8—Flexural Resistance—Composite Sections in Negative Flexure and Noncomposite Sections

6.10.8.1—General

6.10.8.1.1—Discretely Braced Flanges in Compression

At the strength limit state, the following requirement shall be satisfied:

$$f_{bu} + \frac{1}{3} f_t \leq \phi_f F_{nc} \quad (6.10.8.1.1-1)$$

where:

ϕ_f = resistance factor for flexure specified in Article 6.5.4.2

f_{bu} = flange stress calculated without consideration of flange lateral bending determined as specified in Article 6.10.1.6 (ksi)

f_t = flange lateral bending stress determined as specified in Article 6.10.1.6 (ksi)

C6.10.7.2.2

The nominal flexural resistance of noncompact composite sections in positive flexure is limited to the moment at first yield. Thus, the nominal flexural resistance is expressed simply in terms of the flange stress. For noncompact sections, the elastically computed stress in each flange due to the factored loads, determined in accordance with Article 6.10.1.1.1a, is compared with the yield stress of the flange times the appropriate flange-strength reduction factors.

C6.10.7.3

The ductility requirement specified in this Article is intended to protect the concrete deck from premature crushing. The limit of $D_p < 5D'$ in AASHTO (1998) corresponds to $D_p/D_t < 0.5$ for $\beta = 0.75$. The D_p/D_t ratio is lowered to 0.42 in Eq. 6.10.7.3-1 to ensure significant yielding of the bottom flange when the crushing strain is reached at the top of concrete deck for all potential cases. In checking this requirement, D_t should be computed using a lower-bound estimate of the actual thickness of the concrete haunch, or may be determined conservatively by neglecting the thickness of the haunch.

C6.10.8.1.1

Eq. 6.10.8.1.1-1 addresses the resistance of the compression flange by considering this element as an equivalent beam-column. This equation is effectively a beam-column interaction equation, expressed in terms of the flange stresses computed from elastic analysis (White and Grubb, 2005). The f_{bu} term is analogous to the axial load and the f_t term is analogous to the bending moment within the equivalent beam-column member. The factor of one-third in front of the f_t term in Eq. 6.10.8.1.1-1 gives an accurate linear approximation of the equivalent beam-column resistance within the limits on f_t specified in Article 6.10.1.6 (White and Grubb, 2005).

Eqs. 6.10.8.1.1-1, 6.10.8.1.2-1, and 6.10.8.1.3-1 are developed specifically for checking of slender-web noncomposite sections and slender-web composite sections in negative flexure. These equations may be used as a simple conservative resistance check for other types of

F_{nc} = nominal flexural resistance of the flange determined as specified in Article 6.10.8.2 (ksi)

composite sections in negative flexure and noncomposite sections. The provisions specified in Appendix A6 may be used for composite sections in negative flexure and for noncomposite sections with compact or noncompact webs in straight bridges for which the specified minimum yield strengths of the flanges and web do not exceed 70 ksi and for which the flanges satisfy Eq. 6.10.6.2.3-2. The Engineer should give consideration to utilizing the provisions of Appendix A6 for such sections in straight bridges with compact webs; however, Appendix A6 provides only minor increases in the nominal resistance for sections in which the web slenderness approaches the noncompact web limit of Eq. 6.10.6.2.3-1.

6.10.8.1.2—Discretely Braced Flanges in Tension

At the strength limit state, the following requirement shall be satisfied:

$$f_{bu} + \frac{1}{3}f_c \leq \phi_f F_{nt} \quad (6.10.8.1.2-1)$$

where:

F_{nt} = nominal flexural resistance of the flange determined as specified in Article 6.10.8.3 (ksi)

6.10.8.1.3—Continuously Braced Flanges in Tension or Compression

At the strength limit state, the following requirement shall be satisfied:

$$f_{bu} \leq \phi_f R_b F_{yf} \quad (6.10.8.1.3-1)$$

6.10.8.2 Compression Flange Flexural Resistance

6.10.8.2.1—General

Eq. 6.10.8.1.1-1 shall be satisfied for both local buckling and LTB using the appropriate value of F_{nc} determined for each case as specified in Articles 6.10.8.2.2 and 6.10.8.2.3, respectively.

C6.10.8.1.2

Eq. 6.10.8.1.2-1 is an accurate approximation of the full plastic strength of a rectangular flange cross-section subjected to combined vertical and lateral bending within the limit of Eq. 6.10.1.6-1, originally proposed by Hall et al. (1999).

C6.10.8.2.1

All of the I-section compression flange flexural resistance equations of these Specifications are based consistently on the logic of identifying the two anchor points shown in Figure C6.10.8.2.1-1 for the case of uniform major-axis bending. Anchor point 1 is located at the length $L_b = L_p$ for LTB or flange slenderness $b_{fc}/2t_{fc} = \lambda_{pf}$ for FLB corresponding to development of the maximum potential flexural resistance, labeled as F_{max} or M_{max} in the figure, as applicable. Anchor point 2 is located at the length L_r or flange slenderness λ_{rf} for which the inelastic and elastic LTB or FLB resistances are the same. In Article 6.10.8.2.2, this resistance is taken as $R_b F_{yr}$, where F_{yr} is taken as the smaller of $0.7F_{yc}$ and F_{yw} , but not less than $0.5F_{yc}$. With the exception of hybrid sections with F_{yw} significantly smaller than F_{yc} , $F_{yr} = 0.7F_{yc}$. This limit corresponds to a nominal compression flange residual stress effect of $0.3F_{yc}$. The $0.5F_{yc}$ limit on F_{yr} avoids anomalous situations for some types of cross-sections in which the inelastic buckling equation gives a

larger resistance than the corresponding elastic FLB curve. In Article 6.10.8.2.3a, this resistance is taken as $R_b F_{yr}$, where F_{yr} is taken as $0.5F_{yc}$ for members with longitudinally unstiffened webs to account for the combined effects of residual stresses and geometric imperfections on the LTB resistance. For members with longitudinally stiffened webs, F_{yr} is taken as the smaller of $0.5F_{yc}$ and the web bend-buckling resistance, F_{crw} . Also, the $0.5F_{yc}$ limit is equivalent to the implicit value of F_{yr} used in AASHTO (1998). For $L_b > L_r$ or $b_{fc}/2t_{fc} > \lambda_{rf}$, the LTB and FLB resistances are governed by elastic buckling. However, the elastic FLB resistance equations are not specified explicitly in these provisions since the limits of Article 6.10.2.2 preclude elastic FLB for specified minimum yield strengths up to and including $F_{yc} = 90$ ksi. Use of the inelastic FLB Eq. 6.10.8.2.2-2 is permitted for rare cases in which $b_{fc}/2t_{fc}$ can potentially exceed λ_{rf} for $F_{yc} > 90$ ksi.

For unbraced lengths subjected to moment gradient, the LTB resistances for the case of uniform major-axis bending are simply scaled by the moment-gradient modifier C_b , with the exception that the LTB resistance is capped at F_{max} or M_{max} , as illustrated by the dashed line in Figure C6.10.8.2.1-1. The maximum unbraced length at which the LTB resistance is equal to F_{max} or M_{max} under a moment gradient may be determined from Article D6.4.1 or D6.4.2, as applicable. The FLB resistance for moment-gradient cases is the same as that for the case of uniform major-axis bending, neglecting the relatively minor influence of moment-gradient effects.

Figure C6.10.8.2.1-1—Basic Form of All I-section Compression Flange Flexural Resistance Equations

6.10.8.2.2—Local Buckling Resistance

The local buckling resistance of the compression flange shall be taken as:

- If $\lambda_f \leq \lambda_{pf}$, then:

$$F_{nc} = R_b R_h F_{yc} \quad (6.10.8.2.2-1)$$

- Otherwise:

$$F_{nc} = \left[1 - \left(1 - \frac{F_{yr}}{R_b F_{yc}} \right) \left(\frac{\lambda_f - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \right] R_b R_h F_{yc} \quad (6.10.8.2.2-2)$$

in which:

λ_f = slenderness ratio for the compression flange

$$= \frac{b_{fc}}{2t_{fc}} \quad (6.10.8.2.2-3)$$

λ_{pf} = limiting slenderness ratio for a compact flange

$$= 0.38 \sqrt{\frac{E}{F_{yc}}} \quad (6.10.8.2.2-4)$$

λ_{rf} = limiting slenderness ratio for a noncompact flange

$$= 0.56 \sqrt{\frac{E}{F_{yr}}} \quad (6.10.8.2.2-5)$$

where:

F_{yr} = compression-flange stress at the onset of nominal yielding within the cross-section, including residual stress effects, but not including compression flange lateral bending, taken as the smaller of $0.7F_{yc}$ and F_{yw} , but not less than $0.5F_{yc}$

R_b = web load-shedding factor determined as specified in Article 6.10.1.10.2

R_h = hybrid factor determined as specified in Article 6.10.1.10.1

6.10.8.2.3—LTB Resistance

6.10.8.2.3a—General

These provisions shall apply generally to noncomposite unbraced lengths of I-section members as well as composite unbraced lengths of I-section members.

C6.10.8.2.2

Eq. 6.10.8.2.2-4 defines the slenderness limit for a compact flange whereas Eq. 6.10.8.2.2-5 gives the slenderness limit for a noncompact flange. The nominal flexural resistance of a section with a compact flange is independent of the flange slenderness, whereas the flexural resistance of a section with a noncompact flange is expressed as a linear function of the flange slenderness as illustrated in Figure C6.10.8.2.1-1. The compact flange slenderness limit is the same as specified in AISC (2022b) and in AASHTO (1998). For different grades of steel, this slenderness limit is as follows:

Table C6.10.8.2.2-1—Limiting Slenderness Ratio for a Compact Flange

F_{yc} (ksi)	λ_{pf}
36.0	10.8
50.0	9.2
70.0	7.7
90.0	6.8
100.0	6.5

Eq. 6.10.8.2.2-5 is based conservatively on the more general limit given by Eq. A6.3.2-5, but with a FLB coefficient of $k_c = 0.35$. With the exception of hybrid sections with $F_{yw} < 0.7F_{yc}$, the term F_{yr} in Eq. 6.10.8.2.2-5 is always equal to $0.7F_{yc}$.

C6.10.8.2.3a

These provisions address the calculation of the nominal LTB resistance for general composite or noncomposite unbraced lengths with single- or reverse

These provisions are not applicable for I-section members subjected to single-curvature bending in which the flange in flexural compression is continuously braced within the entire unbraced length under consideration. For these types of unbraced lengths, the continuously braced flange shall be checked by the provisions of Article 6.10.7.1, 6.10.7.2, or 6.10.8.1.3, as applicable.

In lieu of a more refined analysis, the nominal LTB resistance of a discretely braced flange subjected to flexural compression shall be calculated at the cross-section where $f_{bu}/R_b R_h F_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections, and shall be taken as:

- If $L_b \leq L_p$, then:

$$F_{nc} = R_b R_h F_{yc} \quad (6.10.8.2.3a-1)$$

- If $L_p < L_b \leq L_r$, then:

$$F_{nc} = C_b \left[1 - \left(1 - \frac{F_{yr}}{R_h F_{yc}} \right) \left(\frac{L_b - L_p}{L_r - L_p} \right) \right] R_b R_h F_{yc} \leq R_b R_h F_{yc} \quad (6.10.8.2.3a-2)$$

- If $L_b > L_r$, then:

$$F_{nc} = R_b F_e \leq R_b R_h F_{yc} \quad (6.10.8.2.3a-3)$$

in which:

L_p = limiting unbraced length to achieve the nominal flexural resistance of $R_b R_h F_{yc}$ under uniform bending (in.)

$$= 1.1 r_t \sqrt{\frac{E}{F_{yr}}} \quad (6.10.8.2.3a-4)$$

L_r = limiting unbraced length to achieve the onset of nominal yielding in either flange under uniform bending considering compression-flange residual stress and geometric imperfection effects (in.)

$$= \pi r_t \sqrt{\frac{E}{F_{yr}}} \quad (6.10.8.2.3a-5)$$

where:

C_b = moment-gradient modifier, calculated as specified in Article 6.10.8.2.3b or 6.10.8.2.3c, as applicable

curvature bending, double- or single-symmetry of the steel cross-section, and prismatic or nonprismatic geometry, including potential steps in F_{yc} along the length. They are based in general on the procedures in AISC Design Guide 25 (White et al., 2021a). The Design Guide 25 fundamental approach is to calculate f_{bu}/F_{nc} at a number of cross-sections in each unbraced length, considering the calculated R_b and R_h values and the value of F_{yc} at each cross-section.

For common practical situations, the maximum f_{bu}/F_{nc} may be calculated with good accuracy as the value at the cross-section having the maximum $f_{bu}/R_b R_h F_{yc}$ over the entire unbraced length, including the end cross-sections because, for elastic LTB, there is only one γ_e . This γ_e is the multiplier by which the calculated design stresses and moments would need to be scaled to reach the theoretical elastic LTB load level as described further in Article C6.10.8.2.3c. For cases where the elastic LTB resistance is calculated directly from an elastic eigenvalue buckling analysis, γ_e is the smallest, or controlling, eigenvalue obtained from the buckling solution.

For unbraced lengths ranging from the simplest case of homogeneous prismatic members with noncompact or compact webs, where R_b and R_h are equal to 1.0, and with constant F_{yc} throughout the unbraced length under consideration, through the most complex cases involving variable web depth members with steps in the cross-section along the length, including steps in F_{yc} , where R_b and R_h vary along the unbraced length:

- The largest f_{bu}/F_{nc} for LTB occurs at the cross-section having the largest $f_{bu}/R_b R_h F_{yc}$ when Eq. 6.10.8.2.3a-1 governs.
- The largest f_{bu}/F_{nc} for LTB occurs at the cross-section having the largest $1/R_b$, or smallest R_b , when Eq. 6.10.8.2.3a-3 governs, unless the elastic LTB stress becomes greater than the plateau strength, $R_b R_h F_{yc}$, in which case the largest f_{bu}/F_{nc} for LTB occurs at the cross-section having the largest $f_{bu}/R_b R_h F_{yc}$.

Eq. 6.10.8.2.3a-4 defines the compact unbraced length limit for a member subjected to uniform major-axis bending, whereas Eq. 6.10.8.2.3a-5 gives the corresponding noncompact unbraced length limit. These limits are consistent with the values employed for slender-web I-section members in the AISC Specification (2022b). The limit in Eq. 6.10.8.2.3a-4 is slightly larger than the limit employed in prior AASHTO LRFD Specifications. The flexural resistance of a member braced at or below the compact limit is independent of the unbraced length, whereas it is expressed as a linear function of the unbraced length for lengths between the compact and noncompact limits, as illustrated in Figure C6.10.8.2.1-1. F_{yr} in Eqs. 6.10.8.2.3a-2 and 6.10.8.2.3a-5 is $0.5F_{yc}$ for I-girders with longitudinally

- f_{bu} = factored flange compressive stress at the cross-section under consideration, calculated without consideration of flange lateral bending (ksi)
- F_{crw} = nominal bend-buckling resistance for a longitudinally stiffened web determined as specified in Article 6.10.1.9.2 (ksi)
- F_e = elastic LTB stress, calculated as specified in Article 6.10.8.2.3b or 6.10.8.2.3c, as applicable (ksi)
- F_{yc} = specified minimum yield strength of the compression flange (ksi)
- F_{yr} = compression-flange stress at the onset of nominal yielding, including residual stress and geometric imperfection effects but not including compression-flange lateral bending, taken as $0.5F_{yc}$ for members with longitudinally unstiffened webs. For members with longitudinally stiffened webs, F_{yr} shall be taken as the smaller of $0.5F_{yc}$ and F_{crw} (ksi)
- L_b = unbraced length (in.)
- R_b = minimum web load-shedding factor within the unbraced length under consideration including the end cross-sections, determined as specified in Article 6.10.1.10.2
- R_h = hybrid factor, determined as specified in Article 6.10.1.10.1
- r_t = radius of gyration for LTB, calculated as specified in Article 6.10.8.2.3b or 6.10.8.2.3c, as applicable (in.)

Article 6.10.8.2.3b shall apply for determining the LTB parameters C_b , F_e , and r_t for prismatic unbraced lengths. Article 6.10.8.2.3c shall apply for determining these parameters for nonprismatic unbraced lengths.

For noncomposite unbraced lengths subjected to reverse curvature bending, the maximum $f_{bu}/R_bR_hF_{yc}$ shall be determined considering both flanges. For unbraced lengths subjected to reverse curvature bending in which one of the flanges is continuously braced, the maximum $f_{bu}/R_bR_hF_{yc}$ shall be determined considering only the flange that is not continuously braced. In this case, the continuously braced flange shall be checked by the provisions of Article 6.10.7.1, 6.10.7.2, or 6.10.8.1.3 as applicable.

unstiffened webs, and the minimum of $0.5F_{yc}$ and F_{crw} for I-girders with longitudinally stiffened webs. This provides a more uniform level of reliability consistent with the target levels in the AISC and AASHTO LRFD Specifications than the variable value of F_{yr} , often equal to $0.7F_{yc}$ in previous Specifications (Subramanian and White, 2017b) (Subramanian et al., 2018) (Slein et al., 2021).

Where a more refined estimate of the LTB resistance accounting for end restraint from adjacent unbraced lengths and/or connection details is desired, the effective unbraced length, $K\ell_b$, may be substituted for the length, L_b , in the LTB equations of this article. Alternatively, the LTB resistance may be based on a direct buckling analysis. Article CD6.6.4 provides guidance pertaining to this type of analysis. Ziemian (2010) and Nethercot and Trahair (1976) present a simple hand method for calculation of elastic LTB effective length factors. The use of half-round I-girder bearing stiffeners at supports can provide increased torsional warping restraint at one or more ends of an unbraced length containing such stiffeners resulting in an increased elastic lateral-torsional buckling resistance, which may be particularly beneficial when investigating stability during construction, and also a smaller effective unbraced length for computing the nominal lateral-torsional buckling resistance, F_{nc} . The increased elastic lateral-torsional buckling resistance can also result in smaller amplification of first-order flange lateral bending stresses in the compression flange within the unbraced length under consideration according to the provisions of Article 6.10.1.6. When such stiffeners are utilized, a lower-bound effective length factor of 0.8 may be assumed when half-round bearing stiffeners are present at both ends of the unbraced length under consideration, or 0.9 when half-round bearing stiffeners are present at only one end of the unbraced length. Quadrato et al. (2014) present an approach to calculate more refined and less conservative values of the effective length factor for such cases.

Note that the most economical solution is not necessarily achieved by limiting the unbraced length to L_p . Setting $L_b \leq L_p$ ensures that the member can achieve the plateau strength, $R_bR_hF_{yc}$, when $C_b = 1.0$. Less restrictive unbraced lengths achieve the plateau strength when C_b is greater than 1.0. Furthermore, the most economical design may be one in which the plateau strength is not achieved, particularly when the moment-gradient modifier, C_b , is close to 1.0.

For cases in single-curvature bending where continuous bracing of a flange subjected to compression ends, the unbraced length is to be taken as the distance from the end of the continuous bracing to the adjacent location of a discrete brace; otherwise, the unbraced length is to be taken as the full unbraced length between the discrete brace locations.

6.10.8.2.3b—LTB Parameters for Prismatic Unbraced Lengths

The moment-gradient modifier, C_b , may be calculated as follows:

$$C_b = \frac{12.5M_{\max}}{2.5M_{\max} + 3M_A + 4M_B + 3M_C} \quad (6.10.8.2.3b-1)$$

where:

M_A, M_B, M_C = absolute value of the factored major-axis bending moment at one-quarter, one-half and three-quarters of the unbraced length under consideration (points A, B, and C), respectively, calculated from the moment envelope values that produce the largest flexural compression in the flange under consideration at these points, or the smallest flexural tension in this flange if the flange is never in compression at the point. For locations A, B, or C in unbraced lengths of noncomposite or composite section members where the flange under consideration is subjected to compression and is continuously braced within either quarter portion of the unbraced length adjacent to the point under consideration, the moment corresponding to that point, A, B, or C, shall be taken equal to zero in Eq. 6.10.8.2.3b-1 (kip-in.)

$M_{\max}$ = absolute value of the factored maximum major-axis moment in the unbraced length, calculated from the moment envelope value that produces the largest flexural compression in the flange under consideration (kip-in.)

The elastic LTB stress, F_e , at the governing cross-section shall be taken as:

$$F_e = \frac{C_b \pi^2 E}{\left(\frac{L_b}{r_t}\right)^2} \quad (6.10.8.2.3b-2)$$

The radius of gyration for LTB, r_t , at the governing cross-section may be taken as:

$$r_t = \frac{b_{fc}}{\sqrt{12 \left(1 + \frac{1}{3} \frac{D_e t_w}{b_{fc} t_{fc}}\right)}} \quad (6.10.8.2.3b-3)$$

where:

b_{fc} = width of the compression flange (in.)

C6.10.8.2.3b

The effect of a variation in the moment along the length between brace points is accounted for by the moment-gradient modifier, C_b . Eq. 6.10.8.2.3b-1 is only applicable for the calculation of C_b for:

- Prismatic composite or noncomposite unbraced lengths subjected to single-curvature bending;
- Prismatic noncomposite unbraced lengths of doubly symmetric members subjected to reverse curvature bending; and
- Prismatic composite unbraced lengths subjected to reverse curvature bending.

C_b from Eq. 6.10.8.2.3b-1 has a base value of 1.0 when the moment and the corresponding flange compressive major-axis bending stress are constant over the unbraced length. C_b may be conservatively taken equal to 1.0 for all cases, with the exception of unusual circumstances involving no bracing within the span and significant top-flange loading, and cantilever beams with flexible backspans and/or significant top-flange loading, as discussed further below. For doubly symmetric noncomposite members with no vertical loading between brace points, C_b from Eq. 6.10.8.2.3b-1 is equal to 1.0 for the case of equal end moments of opposite sign, i.e., uniform bending; 2.27 for the case of equal end moments of the same sign, i.e., reverse curvature bending; and is equal to 1.67 when one end moment equals zero.

For prismatic noncomposite unbraced lengths of singly symmetric members subject to reverse curvature bending, Eq. 6.10.8.2.3b-1 should be multiplied by the factor, R_m , calculated as follows (Reichenbach et al., 2020):

- If $-0.5 < \frac{M_{\text{small}}}{M_{\text{large}}} < 0.0$ and $x_{\text{inf}} \leq \frac{3L_b}{8}$, then:

$$R_m = 1.0 \quad (C6.10.8.2.3b-1)$$

- Otherwise:

$$R_m = 0.5 + 2.0(\rho_{\text{Top}})^2 \quad (C6.10.8.2.3b-2)$$

in which:

ρ_{Top} = degree of monosymmetry parameter

$$= \frac{I_{y \text{ Top}}}{I_y} \quad (C6.10.8.2.3b-3)$$

where:

D_c = depth of the web in compression in the elastic range at the cross-section under consideration (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.

t_f = thickness of the compression flange (in.)

t_w = web thickness (in.)

Where C_b is greater than 1.0, the LTB resistance alternatively may be calculated by the equivalent procedures specified in Article D6.4.1, using the parameters calculated as specified herein.

I_{yTop} = moment inertia of the top flange about the vertical centroidal axis (in.⁴)

I_y = moment of inertia of the section about the vertical centroidal axis (in.⁴)

L_b = unbraced length under consideration (in.)

M_{small} = factored major-axis moment envelope value at the end of the unbraced length under consideration with the smaller magnitude of moment (kip-in.). The ratio of M_{small}/M_{large} should be determined considering the sign of the moments.

M_{large} = factored major-axis moment envelope value at the end of the unbraced length under consideration with the larger magnitude of moment (kip-in.). The ratio of M_{small}/M_{large} should be determined considering the sign of the moments.

x_{inf} = distance between the point of contraflexure and the end of the unbraced length under consideration with the smaller magnitude of moment, M_{small} (in.)

The resulting value of C_b should not exceed 3.0.

Alternatively, for a more refined and potentially accurate solution for prismatic noncomposite unbraced lengths of singly symmetric members subject to reverse curvature bending and for prismatic composite unbraced lengths subject to reverse curvature bending, the provisions of Article 6.10.8.2.3c or A6.3.3.3, as applicable, may be employed to calculate the LTB parameters, with the elastic LTB load ratio, γ_e , calculated using Method A specified in Article D6.6.2 (Slein et al., 2022b).

Strict application of the C_b provisions would require the consideration of the concurrent moments along the unbraced length. However, since concurrent moments are normally not tracked in the analysis, it is convenient and considered acceptable to utilize the factored worst-case moments from the live load moment envelopes in conjunction with other factored moment diagrams for calculation of C_b .

Where C_b is greater than 1.0, indicating the presence of a significant beneficial moment-gradient effect, the LTB resistances may alternatively be calculated by the equivalent procedures specified in Article D6.4.1. Both the equations in this Article and in Article D6.4.1 permit the plateau strength, F_{max} , in Figure C6.10.8.2.1-1 to be reached at larger unbraced lengths when C_b is greater than 1.0. The procedure in Article D6.4.1 allow the Engineer to focus directly on the maximum unbraced length at which the flexural resistance is equal to F_{max} . The use of these equivalent procedures is recommended for prismatic unbraced lengths when C_b values greater than 1.0 are utilized in the design.

Although the calculation of C_b greater than 1.0 in general can result in a dependency of the flexural resistance on the applied loading, and hence subsequent difficulties in load rating, a C_b value only slightly greater

than 1.0 is sufficient in most cases to develop the maximum flexural resistance, F_{max} , for unbraced lengths in the final constructed condition of a bridge. As long as the combination of the brace spacing and $C_b > 1.0$ is sufficient to develop F_{max} , the flexural resistance is independent of the applied loading. Therefore, when $C_b > 1.0$ is used, it is recommended that the unbraced lengths, L_b , at critical locations be selected such that this condition is satisfied in the final constructed condition. The provisions in this Article tend to give values of C_b that are accurate to significantly conservative. Therefore, if the above guidelines are followed in design, it is unlikely that the flexural resistance would differ from F_{max} in any rating situation, particularly if the Engineer was to use a more refined procedure for the rating calculations. Other more refined formulations for C_b are discussed in Ziemian (2010).

The C_b equations in these provisions and in AISI (2022b) both neglect the effect of the location of the applied load relative to the mid-height of the section. For unusual situations with no intermediate cross-bracing and for unbraced cantilevers with significant loading applied at the level of the top flange, the Engineer should consider including load-height effects in the calculation of C_b . In these cases, the associated C_b values can be less than 1.0. Helwig et al. (1997) give equations for consideration of load-height effects in simple or continuous spans, and Dowswell (2004) gives solutions considering these effects in unbraced cantilevers. When $C_b < 1.0$, F_n can be smaller than F_{max} in Figure C6.10.8.2.1-1 even when L_b is less than or equal to L_p . Therefore, for $C_b < 1.0$, the resistance should be calculated from Eq. 6.10.8.2.3a-2 for L_b less than or equal to L_r .

In past practice, points of contraflexure sometimes have been considered as brace points when the influence of moment gradient was not included in the LTB resistance equations. In certain cases, this practice can lead to a substantially unconservative estimate of the flexural resistance. These Specifications do not intend for points of contraflexure to be considered as brace points. The influence of moment gradient may be accounted for correctly through the use of C_b and the effect of restraint from adjacent unbraced segments may be accounted for by using an effective length factor less than 1.0. Suggested values of C_b for compact-web sections, subject to reverse curvature bending with no intermediate bracing or bracing on only one flange, are provided in Yura and Helwig (2010), and in the commentary to Article F1 of AISI (2022b).

Eq. 6.10.8.2.3b-2 is a conservative simplification of Eq. A6.3.3.2-1, which gives effectively the exact beam-theory based solution for the elastic LTB resistance of a doubly symmetric I-section (Timoshenko and Gere, 1961) for the case of uniform major-axis bending when C_b is equal to 1.0 and when r_t is defined as:

$$r_t = \frac{b_{fc}}{\sqrt{12 \left(\frac{h}{d} + \frac{1}{3} \frac{D_e t_w}{b_{fc} t_{fc}} \frac{D^2}{hd} \right)}} \quad (\text{C6.10.8.2.3b-4})$$

where d is the total depth of the steel section and h is the distance between flange centroids. Eq. 6.10.8.2.3b-2 provides an accurate to conservative estimate of the compression flange elastic LTB resistance, including the influence of the distortional flexibility of the web (White, 2008). Eq. 6.10.8.2.3b-3 is a simplification of the above r_t equation obtained by taking $D = h = d$. For shallow girder sections with thick flanges, Eq. 6.10.8.2.3b-3 gives an r_t value that can be as much as three to four percent conservative relative to the exact equation. Use of Eq. C6.10.8.2.3b-4 is permitted for software calculations or if the Engineer requires a more precise calculation of the elastic LTB resistance.

The other key simplification in Eq. 6.10.8.2.3b-2 is that the St. Venant torsional constant, J , is taken equal to zero. This simplification is prudent for slender-web girders without or with web longitudinal stiffening. For these types of sections, the contribution of J to the elastic LTB resistance is small and is likely to be reduced due to distortion of the web into an S shape and the corresponding raking of the compression flange relative to the tension flange. However, for sections that have web slenderness values approaching the noncompact limit given by Eq. 6.10.6.2.3-3 and listed for different yield strengths in Table C6.10.1.10.2-2, the assumption of $J = 0$ is convenient but tends to be conservative.

For sections containing a compact or noncompact web, the use of the equations given in Article A6.3.3 should be considered. For typical flexural members with $D/b_{fc} > 2$ and $I_{yc}/I_{yt} \geq 0.3$, the effect of taking $J = 0$ on the magnitude of the noncompact bracing limit, L_r , is usually smaller than ten percent (White et al., 2001).

Eqs. 6.10.8.2.3b-2 and A6.3.3.2-1 provide one single consistent representation of the elastic LTB resistance for all types of I-section members. These equations give a conservative representation of the elastic LTB resistance of composite I-section members in negative flexure since they neglect the restraint at the level of the tension flange provided by the lateral and torsional stiffness of the deck. For I-section members with relatively large values of D/b_{fc} , D/t_w and t_{fc}/t_w and with limited transverse web stiffening and/or web transverse stiffeners that are not attached to the top flange, the benefits of this torsional restraint on the LTB resistance tend to be small. In these cases, the influence of the torsional restraint from the deck is largely lost due to the distortional flexibility of the web. For slender-web girders, the benefits of this restraint are judged to not be worth the additional complexity associated with a general distortional buckling solution. For typical cross-frame spacings in I-girder bridges, the equations provided herein result in the development of the full plateau

strength when the moment-gradient modifier, C_b , is properly calculated.

The Engineer should note the importance of the web term D_{ctw} within Eq. 6.10.8.2.3b-3. The web term accounts for the destabilizing effects of flexural compression within the web.

If $D_{ctw}/b_{fc}t_{fc}$ in Eq. 6.10.8.2.3b-3 is taken as a representative value of 2.0, this equation reduces to $0.22b_{fc}$. Based on this assumption and $F_{yc} = 50$ ksi, the compact bracing limit is $L_p = 4.3b_{fc}$ and the noncompact bracing limit given by Eq. 6.10.8.2.3a-5 simplifies to $L_r = 24b_{fc}$. Based on these same assumptions, the equations of Articles B6.2.4 and D6.4 give corresponding limits on L_b that are generally larger than $4.3b_{fc}$. The limit given in Article B6.2.4 is sufficient to permit moment redistribution at interior-pier sections of continuous-span members. The limit given in Article D6.4 is sufficient to develop the plateau strength, F_{max} or M_{max} , shown in Figure C6.10.8.2.1-1 in cases involving a moment gradient along the unbraced length for which $C_b > 1.0$.

6.10.8.2.3c—LTB Parameters for Nonprismatic Unbraced Lengths

Moment-gradient effects should be considered in the calculation of the elastic LTB load ratio, γ_e , and the moment-gradient modifier, C_b , in Eq. 6.10.8.2.3a-2 shall be taken as:

$$C_b = 1.0 \quad (6.10.8.2.3c-1)$$

The elastic LTB stress, F_e , shall be calculated as:

$$F_e = \gamma_e f_{bu} \quad (6.10.8.2.3c-2)$$

where f_{bu} is calculated at the location where $f_{bu}/R_b R_h F_{yc}$ is maximum, and γ_e is calculated using one of the methods specified in Article D6.6, as applicable.

The radius of gyration for LTB, r_t , at the governing cross-section shall be taken as:

$$r_t = \frac{L_b}{\pi} \sqrt{\frac{F_e}{E}} \quad (6.10.8.2.3c-3)$$

The ratios of the lateral moments of inertia, I_{yt1}/I_{yt2} and I_{yb1}/I_{yb2} , of the adjacent flanges of each section at cross-section transitions within the unbraced length under consideration should be greater than or equal to 0.5, where:

I_{yb1} = lateral moment of inertia of the bottom flange of the steel section located closer to the brace point with the smaller magnitude of moment, taken about the vertical axis in the plane of the web (in.⁴)

I_{yb2} = lateral moment of inertia of the bottom flange of the steel section located closer to the brace point

C6.10.8.2.3c

Article 6.10.8.2.3c addresses the extension of the more conventional elastic LTB calculation procedures contained in Article 6.10.8.2.3b to the handling of LTB in general nonprismatic unbraced lengths. This extension is grounded in the approach documented in AISC Design Guide 25 (White et al., 2021a), but is configured in the form of an “equivalent r_t ” given by Eq. 6.10.8.2.3c-3 that allows the direct use of Eqs. 6.10.8.2.3a-1 through 6.10.8.2.3a-3 for the calculations. The equivalent r_t is calculated given the elastic LTB load ratio, γ_e , which is a constant by which the calculated design moments and stresses at the governing section would need to be scaled to reach the theoretical elastic LTB load level, as illustrated in Figure C6.10.8.2.3c-1.

(continued on next page)

Figure C6.10.8.2.3c-1—Scaling of the Design Stresses and Moments at the Governing Cross-Section by the Elastic LTB Load Ratio, γ_e , to Reach the Theoretical Elastic LTB Load Level

with the larger magnitude of moment, taken about the vertical axis in the plane of the web (in.⁴)

I_{yt1} = lateral moment of inertia of the top flange of the steel section located closer to the brace point with the smaller magnitude of moment, taken about the vertical axis in the plane of the web (in.⁴)

I_{yt2} = lateral moment of inertia of the top flange of the steel section located closer to the brace point with the larger magnitude of moment, taken about the vertical axis in the plane of the web (in.⁴)

Where a cross-section transition within the unbraced length occurs at a bolted field splice, the thickness of the splice plates should be included in the calculation of I_{yt1} and I_{yb1} ; the thickness of any fillers should not be included. In calculating the nominal LTB resistance of this unbraced length according to the provisions specified herein, the location of the transition shall be taken at the center of the splice and the contribution of the splice plates to the girder section properties shall be ignored.

For unbraced lengths of constant web depth members containing a single cross-section transition to a smaller section at a distance less than or equal to 20 percent of the unbraced length from the brace point with the smaller magnitude of the moment, and where the larger magnitude of the moment occurs within the section with the largest resistance, and where the ratios, I_{yt1}/I_{yt2} and I_{yb1}/I_{yb2} , of the adjacent flanges of each section at the transition are greater than or equal to 0.5, the LTB resistance of the compression flange, F_{nc} , may be determined assuming the member is prismatic using the parameters calculated as specified in Article 6.10.8.2.3b; that is, assuming that the transition does not exist and that the flanges of the section closer to the brace point with the larger magnitude of moment are extended to the brace point with the smaller magnitude of moment. In these cases, the moment-gradient modifier, C_b , from Article 6.10.8.2.3b should be calculated and applied, and L_b also may be modified by an effective length factor. Where the cross-section transition in this case occurs at a bolted field splice, I_{yt1} and I_{yb1} should be calculated as specified above, and the splice plates on the flange subject to compression should extend from the center of the splice at least 40 percent of the distance from the center of the splice to the brace point with the smaller magnitude of the moment.

Figure C6.10.8.2.3c-1 (cont.)—Scaling of the Design Stresses and Moments at the Governing Cross-Section by the Elastic LTB Load Ratio, γ_e , to Reach the Theoretical Elastic LTB Load Level

For cases where the elastic LTB resistance is calculated directly from an elastic eigenvalue buckling analysis, γ_e is the smallest, or controlling, eigenvalue obtained from the buckling solution. In lieu of a more refined analysis, the buckling stress, F_e may be calculated as the value of the elastic buckling stress at the governing cross-section defined as the location where $f_{bu}/R_b R_h F_{yc}$ is maximum. This aspect of the calculations is discussed further in Article C6.10.8.2.3a. Procedures for estimating γ_e are provided in Article D6.6.

For the case of uniform bending, the reduction in the elastic LTB resistance due to a cross-section transition located within the unbraced length of a constant web depth member is approximately five percent when the transition is placed at 20 percent of the unbraced length from one of the brace points and the ratio of the moments of inertia, I_{yt1}/I_{yt2} and I_{yb1}/I_{yb2} , of the adjacent flanges of each section at the transition is equal to 0.5 (Carskaddan and Schilling, 1974). For moment-gradient cases in which the larger bending moment occurs within the section with the largest resistance, where the section transition is placed at or closer than 20 percent of L_b from the brace point with the smaller magnitude of moment, and where the ratio of the lateral moments of inertia, I_{yt1}/I_{yt2} and I_{yb1}/I_{yb2} , of the adjacent flanges of each section is larger than 0.5, the reduction in the LTB resistance is typically less than five percent. The effect of the section transition on the LTB resistance may be neglected whenever the stated conditions are satisfied, and the member may be assumed to be prismatic within that unbraced length. For a constant web depth member with more than one transition, any single transition located at or closer than 20 percent of the unbraced length from the brace point with the smaller magnitude of moment, and with the ratio of the lateral moments of inertia, I_{yt1}/I_{yt2} and

I_{yb1}/I_{yb2} , of the adjacent flanges of each section equal to or larger than 0.5, may be ignored. In such cases, the LTB resistance of the remaining nonprismatic unbraced length may then be computed as specified in Article 6.10.8.2.3c based on the remaining sections.

For unbraced lengths of constant web depth members containing a cross-section transition at a distance greater than 20 percent of the unbraced length from the brace point with the smaller magnitude of moment, or containing a cross-section transition to a smaller section at or closer than 20 percent of the unbraced length from the brace point with the larger magnitude of moment, or with the ratio of the lateral moments of inertia, I_{y1}/I_{y2} and I_{yb1}/I_{yb2} , of the adjacent flanges of each section less than 0.5, the LTB resistance is to be determined as specified in Article 6.10.8.2.3c. In addition, any adjacent section transitions, involving stepping the thickness of the web or the area of the flanges, closer than 25 percent of the unbraced length from each other should be considered to all be a part of the same section transition. The “equivalent” single section transition should be taken as located at the flange transition furthest from the closest brace point.

6.10.8.3—Flexural Resistance Based on Tension-Flange Yielding

The nominal flexural resistance based on tension-flange yielding shall be taken as:

$$F_{nt} = R_h F_{yt} \quad (6.10.8.3-1)$$

where:

R_h = hybrid factor, determined as specified in Article 6.10.1.10.1

6.10.9—Shear Resistance

6.10.9.1—General

At the strength limit state, straight and curved web panels shall satisfy:

$$V_u \leq \phi_v V_n \quad (6.10.9.1-1)$$

where:

ϕ_v = resistance factor for shear, specified in Article 6.5.4.2

V_n = nominal shear resistance determined as specified in Articles 6.10.9.2 and 6.10.9.3 for unstiffened and stiffened webs, respectively (kip)

V_u = factored shear in the web at the section under consideration (kip)

C6.10.8.3

For sections in which $M_{yt} > M_{yc}$, Eq. 6.10.8.3-1 does not control and tension-flange yielding need not be checked, where M_{yc} and M_{yt} are the yield moments with respect to the compression and tension flange, respectively, determined as specified in Article D6.2.

C6.10.9.1

This Article applies to:

- sections without stiffeners,
- sections with transverse stiffeners only, and
- sections with both transverse and longitudinal stiffeners.

A flowchart for determining the shear resistance of I-sections is shown below.

Transverse intermediate stiffeners shall be designed as specified in Article 6.10.11.1. Longitudinal stiffeners shall be designed as specified in Article 6.10.11.3.

Transverse intermediate stiffeners shall be required wherever the factored shear in the web, V_u , exceeds the factored shear resistance, $\phi_v V_n$, for an unstiffened web, where V_n is determined as specified in Article 6.10.9.2.

Interior web panels of nonhybrid and hybrid I-shaped members:

- without a longitudinal stiffener and with a transverse stiffener spacing not exceeding $3D$, or
- with one or more longitudinal stiffeners and with a transverse stiffener spacing not exceeding $2D$

shall be considered stiffened, and the provisions of Article 6.10.9.3 shall apply. Otherwise, the interior web panel shall be considered unstiffened, and the provisions of Article 6.10.9.2 shall apply.

End web panels of nonhybrid and hybrid I-shaped members:

- With or without one or more longitudinal stiffeners and with a transverse stiffener spacing not exceeding $1.5D$

shall be considered stiffened, and the provisions of Article 6.10.9.3 shall apply. Otherwise, the end web panel shall be considered unstiffened, and the provisions of Article 6.10.9.2 shall apply.

Figure C6.10.9.1-1—Flowchart for Shear Design of I-Sections

Unstiffened and stiffened interior web panels are defined according to the maximum transverse stiffener spacing requirements specified in this Article.

The nominal shear resistance of unstiffened web panels in both nonhybrid and hybrid members is defined by either shear yielding or shear buckling, depending on the web slenderness ratio, as specified in Article 6.10.9.2.

The nominal shear resistance of stiffened interior web panels of both nonhybrid and hybrid members, where the section along the entire panel is proportioned to satisfy Eq. 6.10.9.3.2-1, is defined by the shear yielding resistance or the sum of the shear buckling resistance and the post-buckling resistance from tension-field action, as specified in Article 6.10.9.3.2. Otherwise, the shear resistance is taken as the shear resistance given by Eq. 6.10.9.3.2-8. These specifications recognize the potential for web panels of hybrid members to develop post-buckling resistance due to tension-field action. The applicability of these provisions to the shear strength of curved nonhybrid and hybrid webs is addressed by Zureick et al. (2002), White et al. (2001), White and Barker (2008), White et al. (2008), and Jung and White (2006).

For nonhybrid and hybrid members, the nominal shear resistance of end panels in stiffened webs is defined by either shear yielding or shear buckling, as specified in Article 6.10.9.3.3.

6.10.9.2—Nominal Resistance of Unstiffened Webs

The nominal shear resistance of unstiffened webs shall be taken as the shear yielding or shear buckling resistance as follows:

$$V_n = V_{cr} = CV_p \quad (6.10.9.2-1)$$

in which:

$$V_p = 0.58 F_{yw} D t_w \quad (6.10.9.2-2)$$

where:

C = ratio of the shear buckling resistance to the shear yield strength determined by Eqs. 6.10.9.3.2-4, 6.10.9.3.2-5 or 6.10.9.3.2-6, as applicable, with the shear buckling coefficient, k , taken equal to 5.0

V_{cr} = shear yielding or shear buckling resistance (kip)

V_n = nominal shear resistance (kip)

V_p = plastic shear force (kip)

6.10.9.3—Nominal Resistance of Stiffened Webs

6.10.9.3.1—General

The nominal shear resistance of transversely and longitudinally stiffened interior web panels shall be taken as the shear yielding resistance or the sum of the shear buckling resistance and the post-buckling shear resistance due to tension-field action as specified in Article 6.10.9.3.2. The nominal shear resistance of transversely or transversely and longitudinally stiffened end web panels shall be taken as the shear yielding or shear buckling resistance as specified in Article 6.10.9.3.3. The total web depth, D , shall be used in determining the nominal shear resistance of web panels with longitudinal stiffeners. The required transverse stiffener spacing shall be calculated using the maximum shear in a panel.

Stiffeners shall satisfy the requirements specified in Article 6.10.11.

6.10.9.3.2—Interior Panels

The nominal shear resistance of an interior web panel complying with the provisions of Article 6.10.9.1, and with the section along the entire panel proportioned such that:

$$\frac{2Dt_w}{(b_{fc}t_{fc} + b_{ft}t_{ft})} \leq 2.5 \quad (6.10.9.3.2-1)$$

shall be taken as:

C6.10.9.2

The consideration of tension-field action (Basler, 1961) is not permitted for unstiffened web panels. The shear yielding or shear buckling resistance is calculated as the product of the constant, C , specified in Article 6.10.9.3.2 times the plastic shear force, V_p , given by Eq. 6.10.9.2-2. The plastic shear force is equal to the web area times the assumed shear yield strength of $F_{yw}/\sqrt{3}$. The shear buckling coefficient, k , to be used in calculating the constant, C , is defined as 5.0 for unstiffened web panels, which is a conservative approximation of the exact value of 5.35 for an infinitely long strip with simply supported edges (Timoshenko and Gere, 1961). The nominal shear resistance is equal to the shear yielding resistance when C is equal to 1.0; otherwise, the nominal shear resistance is equal to the shear buckling resistance.

C6.10.9.3.1

Longitudinal stiffeners divide a web panel into subpanels. In Cooper (1967), the shear resistance of the entire panel is taken as the sum of the shear resistance of the subpanels. However, the contribution to the shear resistance of a single longitudinal stiffener located at its optimum position for flexure is relatively small. Thus, it is conservatively specified that the influence of the longitudinal stiffener be neglected in computing the nominal shear resistance of the web plate.

C6.10.9.3.2

Stiffened interior web panels of nonhybrid and hybrid members satisfying Eq. 6.10.9.3.2-1 are capable of developing post-buckling shear resistance due to tension-field action (Basler, 1961) (White et al., 2004). This action is analogous to that of the tension diagonals of a Pratt truss. The nominal shear resistance of these panels can be computed by summing the contributions of beam action and post-buckling tension-field action. The resulting expression is given in Eq. 6.10.9.3.2-2, where the first term in the bracket relates to either the shear yield or shear buckling force and the

$$V_n = V_p \left[C + \frac{0.87(1-C)}{\sqrt{1 + \left(\frac{d_o}{D}\right)^2}} \right] \quad (6.10.9.3.2-2)$$

in which:

$$V_p = 0.58 F_{yw} D t_w \quad (6.10.9.3.2-3)$$

where:

- b_{fc} = width of the compression flange (in.)
- b_{ft} = width of the tension flange (in.)
- t_{fc} = thickness of the compression flange (in.)
- t_{ft} = thickness of the tension flange (in.)
- t_w = web thickness (in.)
- d_o = transverse stiffener spacing (in.)
- V_n = nominal shear resistance of the web panel (kip)
- V_p = plastic shear force (kip)
- C = ratio of the shear buckling resistance to the shear yield strength

The ratio, C , shall be determined as specified below:

- If $\frac{D}{t_w} \leq 1.12 \sqrt{\frac{Ek}{F_{yw}}}$, then:

$$C = 1.0 \quad (6.10.9.3.2-4)$$

- If $1.12 \sqrt{\frac{Ek}{F_{yw}}} < \frac{D}{t_w} \leq 1.40 \sqrt{\frac{Ek}{F_{yw}}}$, then:

$$C = \frac{1.12}{\frac{D}{t_w}} \sqrt{\frac{Ek}{F_{yw}}} \quad (6.10.9.3.2-5)$$

- If $\frac{D}{t_w} > 1.40 \sqrt{\frac{Ek}{F_{yw}}}$, then:

$$C = \frac{1.57}{\left(\frac{D}{t_w}\right)^2} \left(\frac{Ek}{F_{yw}}\right) \quad (6.10.9.3.2-6)$$

in which:

$$k = \text{shear buckling coefficient} \\ = 5 + \frac{5}{\left(\frac{d_o}{D}\right)^2} \quad (6.10.9.3.2-7)$$

second term relates to the post-buckling tension-field force. If Eq. 6.10.9.3.2-1 is not satisfied, the total area of the flanges within the panel is small relative to the area of the web and the full post-buckling resistance generally cannot be developed (White et al., 2004). However, it is conservative in these cases to use the post-buckling resistance given by Eq. 6.10.9.3.2-8. Eq. 6.10.9.3.2-8 gives the solution neglecting the increase in stress within the wedges of the web panel outside of the tension band implicitly included within the Basler model (Gaylord, 1963) (Salmon et al., 2009).

Within the restrictions specified by Eqs. 6.10.9.3.2-1 and 6.10.2.2-2 in general, and Article 6.10.9.3.1 for longitudinally stiffened I-girders in particular, and provided that the maximum moment within the panel is utilized in checking the flexural resistance, White et al. (2004) show that the equations of these Specifications sufficiently capture the resistance of a reasonably comprehensive body of experimental test results without the need to consider moment-shear interaction. In addition, the additional shear resistance and anchorage of tension-field action provided by a composite deck are neglected within the shear resistance provisions of these Specifications. Also, the maximum moment and shear envelope values are typically used for design, whereas the maximum concurrent moment and shear values tend to be less critical. These factors provide some additional margin of conservatism beyond the sufficient level of safety obtained if these factors do not exist. Therefore, previous provisions related to the effects of moment-shear interaction are not required in these Specifications.

The coefficient, C , is equal to the ratio of the elastic buckling stress of the panel, computed assuming simply supported boundary conditions, to the shear yield strength assumed to equal $F_{yw}/\sqrt{3}$. Eq. 6.10.9.3.2-6 is applicable only for C values not exceeding 0.8 (Basler, 1961). Above 0.8, C values are given by Eq. 6.10.9.3.2-5 until a limiting slenderness ratio is reached where the shear buckling stress is equal to the shear yield strength and $C = 1.0$. Eq. 6.10.9.3.2-7 for the shear buckling coefficient is a simplification of two exact equations for k that depend on the panel aspect ratio.

Otherwise, the nominal shear resistance shall be taken as follows:

$$V_n = V_p \left[C + \frac{0.87(1-C)}{\left(\sqrt{1 + \left(\frac{d_o}{D} \right)^2} + \frac{d_o}{D} \right)} \right] \quad (6.10.9.3.2-8)$$

6.10.9.3.3—End Panels

The nominal shear resistance of a stiffened web end panel shall be taken as:

$$V_n = V_{cr} = CV_p \quad (6.10.9.3.3-1)$$

in which:

$$V_p = 0.58 F_{yw} D t_w \quad (6.10.9.3.3-2)$$

where:

- C = ratio of the shear buckling resistance to the shear yield strength determined by Eqs. 6.10.9.3.2-4, 6.10.9.3.2-5, or 6.10.9.3.2-6, as applicable
 V_{cr} = shear yielding or shear buckling resistance (kip)
 V_p = plastic shear force (kip)

The transverse stiffener spacing for stiffened end panels with or without longitudinal stiffeners shall not exceed $1.5D$.

6.10.10—Shear Connectors

6.10.10.1—General

In composite sections, stud shear connectors shall be provided at the interface between the concrete deck and the steel section to resist the interface shear.

Simple-span composite bridges shall be provided with shear connectors throughout the length of the span.

Straight continuous composite bridges should normally be provided with shear connectors throughout the length of the bridge. In the negative flexure regions, shear connectors shall be provided where the longitudinal reinforcement is considered to be a part of the composite section. Otherwise, shear connectors need not be provided in negative flexure regions, but additional connectors shall be placed in the region of the points of permanent load contraflexure as specified in Article 6.10.10.3.

Where shear connectors are omitted in negative flexure regions, the longitudinal reinforcement shall be extended into the positive flexure region as specified in Article 6.10.1.7.

C6.10.9.3.3

The shear in stiffened end panels adjacent to simple supports is limited to either the shear yielding or shear buckling resistance given by Eq. 6.10.9.3.3-1 in order to provide an anchor for the tension field in adjacent interior panels. The shear buckling coefficient, k , to be used in determining the constant, C , in Eq. 6.10.9.3.3-1 is to be calculated based on the spacing from the support to the first stiffener adjacent to the support, which may not exceed $1.5D$.

C6.10.10.1

Shear connectors help control cracking in regions of negative flexure where the deck is subject to tensile stress and has longitudinal reinforcement.

Curved continuous composite bridges shall be provided with shear connectors throughout the length of the bridge.

6.10.10.1.1—Types

Stud shear connectors shall be designed by the provisions of this Article.

Shear connectors should be of a type that permits a thorough compaction of the concrete to ensure that their entire surfaces are in contact with the concrete. The connectors shall be capable of resisting both horizontal and vertical movement between the concrete and the steel.

The ratio of the total height to the shank diameter of a stud shear connector shall not be less than 5.0 when embedded in normal weight concrete and 7.0 when embedded in lightweight concrete.

6.10.10.1.2—Pitch

Shear connector pitch shall be determined to satisfy the fatigue limit state, as specified herein and in Articles 6.10.10.2 and 6.10.10.3. The resulting number of shear connectors shall not be less than the number required to satisfy the strength limit state as specified in Article 6.10.10.4.

If regularly spaced shear connectors are used, then the center-to-center pitch between shear connectors, p , shall satisfy:

$$p \leq \frac{n_s Z_r}{V_{sr}} \quad (6.10.10.1.2-1)$$

If shear connector clusters are used, then the center-to-center pitch between clusters, p , shall satisfy:

$$p \leq \frac{2n_s Z_r}{V_{sr}} + s(n_s - 1) \quad (6.10.10.1.2-2)$$

in which:

V_{sr} = horizontal fatigue shear range per unit length (kip/in.)

$$= \sqrt{(V_{fat})^2 + (F_{fat})^2} \quad (6.10.10.1.2-3)$$

V_{fat} = longitudinal fatigue shear range per unit length (kip/in.)

Shear connectors are to be provided in regions of negative flexure in curved continuous bridges because torsional shear exists and is developed in the full composite section along the entire bridge. For bridges containing one or more curved segments, the effects of curvature usually extend beyond the curved segment. Therefore, it is conservatively specified that shear connectors be provided along the entire length of the bridge in this case as well.

C6.10.10.1.1

The experimental testing used to develop the specifications on shear studs was conducted using headed shear studs with a shank diameter of 1.25 in. or smaller.

The specified limits on the total height-to-shank diameter of a stud shear connector are discussed further in Article C6.10.10.4.3.

C6.10.10.1.2

At the fatigue limit state, shear connectors are designed for the range of live load shear between the deck and top flange of the girder. In straight girders, the shear range normally is due to only major-axis bending if torsion is ignored. Curvature, skew and other conditions may cause torsion, which introduces a radial component of the horizontal shear. These provisions provide for consideration of both of the components of the shear to be added vectorially according to Eq. 6.10.10.1.2-3.

Shear stud connectors can be placed in one of two configurations: regularly spaced or clusters. Regularly spaced shear connectors have historically been used for most applications, whereas shear connector clusters, such as those shown in Figure C6.10.10.1.2-1, are commonly used in accelerated bridge construction applications with precast concrete decks but can also be used in conventional construction. Research by Ovuoba and Prinz (2018) and Hillhouse and Prinz (2020) has indicated increased shear demand in the outer rows of clustered configurations that is captured by Eq. 6.10.10.1.2-2. Refer to Article C6.10.10.1.4 for further guidance on the height of clustered shear connectors.

$$= \frac{V_f Q}{I} \quad (6.10.10.1.2-4)$$

F_{fat} = radial fatigue shear range per unit length (kip/in.) taken as the larger of either:

$$F_{fat1} = \frac{A_{bot} \sigma_{flg} \ell}{wR} \quad (6.10.10.1.2-5)$$

or:

$$F_{fat2} = \frac{F_{rc}}{w} \quad (6.10.10.1.2-6)$$

where:

σ_{flg} = range of longitudinal fatigue stress in the bottom flange without consideration of flange lateral bending (ksi)

A_{bot} = area of the bottom flange (in.²)

F_{rc} = net range of cross-frame or diaphragm force at the top flange (kip)

I = moment of inertia of the short-term composite section (in.⁴)

ℓ = distance between brace points (ft)

n_ℓ = number of stud rows in a shear connector cluster along the longitudinal axis

n_t = number of shear connectors in a transverse cross-section

p = center-to-center pitch between regularly spaced shear connectors or center-to-center pitch between shear connector clusters along the longitudinal axis (in.)

Q = first moment of the transformed short-term area of the concrete deck about the neutral axis of the short-term composite section (in.³)

R = minimum girder radius within the panel (ft)

s = center-to-center spacing between studs within a shear connector cluster (in.)

V_f = vertical shear force range under the applicable fatigue load combination specified in Table 3.4.1-1 with the fatigue live load taken as specified in Article 3.6.1.4 (kip)

w = effective length of deck (in.) taken as 48.0 in., except at end supports where w may be taken as 24.0 in.

Z_r = shear fatigue resistance of an individual shear connector determined as specified in Article 6.10.10.2 (kip)

For straight spans or segments, the radial fatigue shear range from Eq. 6.10.10.1.2-5 may be taken equal to zero. For straight or horizontally curved bridges with skews not exceeding 20 degrees, the radial fatigue shear range from Eq. 6.10.10.1.2-6 may be taken equal to zero.

The center-to-center pitch of regularly spaced shear connectors or shear connector clusters shall not exceed

Figure C6.10.10.1.2-1—Shear Connector Cluster having a Repeated Group of Three or More Equally Spaced Shear Connector Rows Spaced along the Longitudinal Beam Axis

The parameters I and Q should be determined using the deck within the effective flange width. However, in negative flexure regions of straight girders only, the parameters I and Q may be determined using the longitudinal reinforcement within the effective flange width for negative moment, unless the concrete deck is considered to be effective in tension for negative moment in computing the range of the longitudinal stress, as permitted in Article 6.6.1.2.1.

The maximum longitudinal fatigue shear range, V_{fat} , is produced by placing the fatigue live load immediately to the left and to the right of the point under consideration. For the load in these positions, positive moments are produced over significant portions of the girder length. Thus, the use of the full composite section, including the concrete deck, is reasonable for determining the stiffness used to determine the shear range along the entire span. Also, the horizontal shear force in the deck is most often considered to be effective along the entire span in the analysis. To satisfy this assumption, the shear force in the deck should be developed along the entire span. For straight girders, an option is permitted to ignore the concrete deck in computing the shear range in regions of negative flexure, unless the concrete is considered to be effective in tension in computing the range of the longitudinal stress, in which case the shear force in the deck must be developed. If the concrete is ignored in these regions, the maximum pitch specified at the end of this Article must not be exceeded.

The radial shear range, F_{fat} , typically is determined for the fatigue live load positioned to produce the largest positive and negative major-axis bending moments in the span. Therefore, vectorial addition of the longitudinal and radial components of the shear range is conservative because the longitudinal and radial shears are not produced by concurrent loads.

Eq. 6.10.10.1.2-5 may be used to determine the radial fatigue shear range resulting from the effect of any curvature between brace points. The shear range is taken as the radial component of the maximum longitudinal range of force in the bottom flange between brace points, which is used as a measure of the major-axis bending moment. The radial shear range is distributed over an effective length of girder flange, w . At end supports, w is halved. Eq. 6.10.10.1.2-5 gives the same units as V_{fat} .

Eq. 6.10.10.1.2-6 will typically govern the radial fatigue shear range where torsion is caused by effects

48.0 in. for members having a web depth greater than or equal to 24.0 in. For members with a web depth less than 24.0 in., the center-to-center pitch of regularly spaced shear connectors or shear connector clusters shall not exceed 24.0 in. For all web depths, the center-to-center pitch of regularly spaced shear connectors or center-to-center pitch between studs within a shear connector cluster shall also not be less than four stud diameters.

other than curvature, such as skew. Eq. 6.10.10.1.2-6 is most likely to control when discontinuous cross-frame or diaphragm lines are used in conjunction with skew angles exceeding 20 degrees in either a straight or horizontally curved bridge. For all other cases, F_{rc} can be taken equal to zero. Eqs. 6.10.10.1.2-5 and 6.10.10.1.2-6 yield approximately the same value if the span or segment is curved and there are no other sources of torsion in the region under consideration. Note that F_{rc} represents the resultant range of horizontal force from all cross-frames or diaphragms at the point under consideration due to the factored fatigue load plus impact that is resisted by the shear connectors. In lieu of a refined analysis, F_{rc} may be taken as 25.0 kips for an exterior girder, which is typically the critical girder.

Eqs. 6.10.10.1.2-5 and 6.10.10.1.2-6 are provided to ensure that a load path is provided through the shear connectors to satisfy equilibrium at a transverse section through the girders, deck, and cross-frame or diaphragm.

The basis for the previous 24.0 in. maximum center-to-center spacing of shear studs for beams or girders of all web depths was based on scaled experiments in the 1940s that recommended a maximum pitch of three to four slab thicknesses, as described further in Yura et al. (2008). More recent test results (Badie and Tadros, 2008) (Provines and Ocel, 2014) have shown that placing shear connectors at a pitch of up to 48.0 in. has no negative effect on the global flexural resistance of composite steel members. The research did not test shallow web depths with long pitches, so the maximum pitch is limited to 24.0 in. for web depths less than 24.0 in. to ensure that designs stay within the bounds that have proven satisfactory in experiments. Large- and small-scale experimental testing has also shown that shear connectors can be placed at a minimum center-to-center pitch of four times the stud diameter without any reduction in strength or fatigue resistance (Provines et al., 2019).

6.10.10.1.3—Transverse Spacing

Stud shear connectors placed transversely across the top flange of the steel section shall not be closer than 4.0 stud diameters center-to-center transverse to the longitudinal axis of the supporting member.

The clear distance between the edge of the top flange and the edge of the nearest shear connector shall not be less than 1.0 in.

C6.10.10.1.3

Large- and small-scale experimental testing has shown that shear studs can be spaced at a 4.0 stud diameter center-to-center transverse spacing with no reduction in strength or fatigue resistance (Provines et al., 2019).

6.10.10.1.4—Cover and Penetration

The clear depth of concrete cover over the tops of the shear connectors should not be less than 2.0 in. Shear connectors should be detailed to penetrate at least 2.0 in. into the concrete deck. Shear connectors on members in structures that are not load path redundant shall be detailed to penetrate at least above the bottom mat of deck reinforcement.

C6.10.10.1.4

Stud shear connectors should penetrate through the haunch between the bottom of the deck and the top flange, if present, and into the deck. Otherwise, the haunch should be reinforced to contain the stud connector and develop its load in the deck. It is recommended that the specified cover and penetration minimums be shown in the contract documents, with the stud height to be detailed

based on field measurements of the actual beam or girder elevations.

When shear connectors are clustered together, it is recommended they extend beyond the bottom mat of deck reinforcement so they are anchored into to the deck core to better resist the elevated forces from clustering the studs closely together (Badie et al., 2018).

Shear connectors on members in structures that are not load path redundant are to be detailed to penetrate at least above the bottom mat of deck reinforcement to provide additional ductility. In addition, the longitudinal and transverse spacing of shear studs as well as haunch height and concrete deck reinforcement must be considered if the shear studs are expected to contribute to carrying vertical tensile forces during a redundancy analysis (Mouras et al., 2008).

6.10.10.2—Fatigue Resistance

The fatigue shear resistance of an individual stud shear connector, Z_r , shall be taken as:

$$Z_r = (\Delta F)_n A_{sc} \quad (6.10.10.2-1)$$

where:

$(\Delta F)_n$ = nominal fatigue resistance, determined as specified in Article 6.6.1.2.5 using the applicable values specified for Condition 9.2 in Table 6.6.1.2.3-1 (ksi)

A_{sc} = cross-sectional area of a stud shear connector (in.²)

C6.10.10.2

Fatigue design of shear connectors was first adopted in the 1966 Interims to the 9th Edition of the AASHTO *Standard Specifications for Highway Bridges*. The original provisions for the fatigue design of shear connectors were based on a semi-log format; i.e., curved in the finite-life region on a log-log plot (Slutter and Fisher, 1966). When load-induced fatigue design was first introduced in the 1974 Interims to the 11th Edition of the AASHTO *Standard Specifications for Highway Bridges*, all other steel bridge details were assigned a slope of 1 to 3 in the finite-life region on a log-log plot. However, shear studs remained in a semi-log format until the 10th Edition of the AASHTO *LRFD Bridge Design Specifications*. A regression of historical shear connector fatigue-test data indicated that the nominal fatigue resistance of stud shear connectors, $(\Delta F)_n$, fits better in a log-log format with a slope of 1 to 5 in the finite-life region, a detail category constant, A, of $1040 \times 10^8 \text{ ksi}^5$, and a constant-amplitude fatigue threshold, $(\Delta F)_{TH}$, of 7.0 ksi, which is reflected in Condition 9.2 in Table 6.6.1.2.3-1 (Provines et al., 2019). The shallower slope in the finite-life region is primarily because shear studs fail in fatigue due to shear stresses rather than tensile stresses.

6.10.10.3—Special Requirements for Points of Permanent Load Contraflexure

For members that are noncomposite for negative flexure in the final condition, additional shear connectors shall be provided in the region of points of permanent load contraflexure.

The number of additional connectors, n_{ac} , shall be taken as:

$$n_{ac} = \frac{A_s f_{sr}}{Z_r} \quad (6.10.10.3-1)$$

where:

C6.10.10.3

The purpose of the additional connectors is to develop the fatigue force in the longitudinal reinforcement due to the negative factored fatigue live load moment at the interior support.

- A_s = total area of longitudinal reinforcement over the interior support within the effective concrete deck width (in.²)
- f_{sr} = stress range in the longitudinal reinforcement at the interior support under the applicable Fatigue load combination specified in Table 3.4.1-1 with the fatigue live load taken as specified in Article 3.6.1.4 (ksi)
- Z_r = fatigue shear resistance of an individual shear connector determined as specified in Article 6.10.10.2 (kip)

The additional shear connectors shall be placed within a distance extending one-third of the effective flange width specified in Article 4.6.2.6 from each side of the point of steel dead load contraflexure. The center-to-center pitch of all connectors, including the additional connectors, within that distance shall satisfy the maximum and minimum pitch requirements specified in Article 6.10.10.1.2. Field splices should be placed so as not to interfere with the shear connectors.

6.10.10.4—Strength Limit State

6.10.10.4.1—General

The factored shear resistance of a single shear connector, Q_r , at the strength limit state shall be taken as:

$$Q_r = \phi_{sc} Q_n \quad (6.10.10.4.1-1)$$

where:

- Q_n = nominal shear resistance of a single shear connector, determined as specified in Article 6.10.10.4.3 (kip)
- ϕ_{sc} = resistance factor for shear connectors specified in Article 6.5.4.2

At the strength limit state, the minimum number of shear connectors, n , over the region under consideration shall be taken as:

$$n = \frac{P}{Q_r} \quad (6.10.10.4.1-2)$$

where:

- P = total nominal shear force, determined as specified in Article 6.10.10.4.2 (kip)
- Q_r = factored shear resistance of one shear connector determined from Eq. 6.10.10.4.1-1 (kip)

6.10.10.4.2—Nominal Shear Force

For simple spans and for continuous spans that are noncomposite for negative flexure in the final condition, the total nominal shear force, P , between the

C6.10.10.4.2

Composite beams with either regularly spaced shear connectors or shear connector clusters have exhibited similar ultimate strength and deflection at

point of maximum positive design live load plus impact moment and each adjacent point of zero moment shall be taken as:

$$P = \sqrt{P_p^2 + F_p^2} \quad (6.10.10.4.2-1)$$

in which:

P_p = total longitudinal force in the concrete deck at the point of maximum positive live load plus impact moment (kip) taken as the lesser of either:

$$P_{1p} = 0.85 f_c' b_s t_s \quad (6.10.10.4.2-2)$$

or

$$P_{2p} = F_{yw} D t_w + F_{y1} b_{f1} t_{f1} + F_{yc} b_{fc} t_{fc} \quad (6.10.10.4.2-3)$$

F_p = total radial force in the concrete deck at the point of maximum positive live load plus impact moment (kip) taken as:

$$F_p = P_p \frac{L_p}{R} \quad (6.10.10.4.2-4)$$

where:

b_s = effective width of the concrete deck (in.)
 L_p = arc length between an end of the girder and an adjacent point of maximum positive live load plus impact moment (ft)
 R = minimum girder radius over the length, L_p (ft)
 t_s = thickness of the concrete deck (in.)

For straight spans or segments, F_p may be taken equal to zero.

For continuous spans that are composite for negative flexure in the final condition, the total nominal shear force, P , between the point of maximum positive design live load plus impact moment and an adjacent end of the member shall be determined from Eq. 6.10.10.4.2-1. The total nominal shear force, P , between the point of maximum positive design live load plus impact moment and the centerline of an adjacent interior support shall be taken as:

$$P = \sqrt{P_T^2 + F_T^2} \quad (6.10.10.4.2-5)$$

in which:

P_T = total longitudinal force in the concrete deck between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support (kip) taken as:

service loads in large-scale experimental tests (Provines et al., 2019). Only a slight deformation in the concrete and the more heavily stressed connectors are needed to redistribute the horizontal shear to other less heavily stressed connectors. The important consideration is that the total number of connectors be sufficient to develop the nominal longitudinal force, P_n , on either side of the point of maximum design live load plus impact moment.

The point of maximum design live load plus impact moment is specified because it applies to the composite section and is easier to locate than a maximum of the sum of the moments acting on the composite section.

For continuous spans that are noncomposite for negative flexure in the final condition, points of zero moment within the span should be taken as the points of steel dead load contraflexure.

For continuous spans that are composite for negative flexure in the final condition, sufficient shear connectors are required to transfer the ultimate tensile force in the reinforcement from the concrete deck to the steel section. The number of shear connectors required between points of maximum positive design live load plus impact moment and the centerline of an adjacent interior support is computed from the sum of the critical forces at the maximum positive and negative moment locations. Since there is no point where moment always changes sign, many shear connectors resist reversing action in the concrete deck depending on the live load position. However, the required number of shear connectors is conservatively determined from the sum of the critical forces at the maximum moment locations to provide adequate shear resistance for any live load position.

The tension force in the deck given by Eq. 6.10.10.4.2-8 is defined as 45 percent of the specified 28-day compressive strength of the concrete. This is a conservative approximation to account for the combined contribution of both the longitudinal reinforcement and also the concrete that remains effective in tension based on its modulus of rupture. A more precise value may be substituted.

The radial effect of curvature is included in Eqs. 6.10.10.4.2-4 and 6.10.10.4.2-9. For curved spans or segments, the radial force is required to bring into equilibrium the smallest of the longitudinal forces in either the deck or the girder. When computing the radial component, the longitudinal force is conservatively assumed to be constant over the entire length L_p or L_n , as applicable.

$$P_T = P_p + P_n \quad (6.10.10.4.2-6)$$

P_n = total longitudinal force in the concrete deck over an interior support (kip) taken as the lesser of either:

$$P_{In} = F_{yw}Dt_w + F_{yt}b_{ft}t_{ft} + F_{yc}b_{fc}t_{fc} \quad (6.10.10.4.2-7)$$

or:

$$P_{2n} = 0.45f'_c b_s t_s \quad (6.10.10.4.2-8)$$

F_T = total radial force in the concrete deck between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support (kip) taken as:

$$F_T = P_T \frac{L_n}{R} \quad (6.10.10.4.2-9)$$

where:

L_n = arc length between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support (ft)

R = minimum girder radius over the length, L_n (ft)

For straight spans or segments, F_T may be taken equal to zero.

6.10.10.4.3—Nominal Shear Resistance

The nominal shear resistance of one stud shear connector embedded in a concrete deck shall be taken as:

$$Q_n = 0.70A_{sc}F_u \quad (6.10.10.4.3-1)$$

where:

A_{sc} = cross-sectional area of a stud shear connector (in.²)

F_u = specified minimum tensile strength of a stud shear connector, determined as specified in Article 6.4.4 (ksi)

C6.10.10.4.3

Prior editions of the specifications relied upon a two-part shear connector strength equation based on the minimum of the steel tensile strength and the bearing strength of the connector on the concrete. The concrete portion of strength came from Ollgaard et al. (1971). An analysis of shear connector strength tests (Pallares and Hajjar, 2010) found that once the total height-to-shank diameter ratio of a stud is 5.0 or greater for normal weight concrete or 7.0 or greater for lightweight concrete, the shear resistance of a connector is controlled solely by a proportion of the connector tensile strength. The 0.70 factor accounts for a shear-to-tensile strength factor found in the analysis along with an adjustment to experimental database values to attain a target reliability. The analysis showed that if a shear-to-tensile strength factor of 0.70 was used, then using $\phi_{sc} = 1.0$ is appropriate. Experimental testing has also verified that for shear studs embedded in non-shrink grout, having a shear stud total height-to-shank diameter ratio of approximately 7.0 ensures that the strength of the connection is also dependent only on a proportion of the connector tensile strength (Provines et. al., 2019).

6.10.11—Web Stiffeners**6.10.11.1—Web Transverse Stiffeners***6.10.11.1.1—General*

Transverse stiffeners shall consist of plates or angles welded or bolted to either one or both sides of the web.

Stiffeners in straight girders not used as connection plates shall be tight-fit or attached at the compression flange, but need not be in bearing with the tension flange. Single-sided stiffeners on horizontally curved girders should be attached to both flanges. When pairs of transverse stiffeners are used on horizontally curved girders, they shall be fitted tightly or attached to both flanges.

Stiffeners used as connecting plates for diaphragms or cross-frames shall be attached to both flanges.

The distance between the end of the web-to-stiffener weld and the near edge of the adjacent web-to-flange weld shall not be less than $4t_w$, but shall not exceed the lesser of $6t_w$ and 4.0 in.

Transverse stiffeners with a spacing not exceeding $2D$ shall be provided in web panels with longitudinal stiffeners.

C6.10.11.1.1

When single-sided transverse stiffeners are used on horizontally curved girders, they should be attached to both flanges to help retain the cross-sectional configuration of the girder when subjected to torsion and to avoid high localized bending within the web. This is particularly important at the top flange due to the torsional restraint from the slab. The fitting of pairs of transverse stiffeners against the flanges, or attachment to both flanges, is required for the same reason.

The minimum distance between the end of the web-to-stiffener weld to the adjacent web-to-flange weld is specified to relieve flexing of the unsupported segment of the web to avoid fatigue-induced cracking of the stiffener-to-web welds. The $6t_w$ -criterion for maximum distance is specified to avoid vertical buckling of the unsupported web. The 4.0-in. criterion was arbitrarily selected to avoid a large unsupported length where the web thickness has been selected for reasons other than stability, e.g., webs of bascule girders at trunnions.

Web panels with longitudinal stiffeners must include transverse stiffeners at a spacing of $2D$ or less, whether or not they are required for shear, in order to provide support to the longitudinal stiffeners along their length, and because all available supporting experimental and simulation data for the design of longitudinally stiffened girders is from specimens that included transverse stiffeners, with panel aspect ratios generally less than or equal to 2.0 (Subramanian and White, 2016a and 2017c).

The size of intermediate stiffeners should be kept the same along the length of the girders to eliminate multiple plate sizes and eliminate the possibility of placement errors.

6.10.11.1.2—Projecting Width

The width, b_i , of each projecting stiffener element shall satisfy:

$$b_i \geq 2.0 + \frac{D}{30} \quad (6.10.11.1.2-1)$$

and:

$$16t_p \geq b_i \geq b_f / 4 \quad (6.10.11.1.2-2)$$

where:

b_f = for I-sections, full width of the widest compression flange within the field section under consideration; for tub sections, full width

C6.10.11.1.2

Eq. 6.10.11.1.2-1 is taken from Ketchum (1920). This equation tends to govern relative to Eq. 6.10.11.1.2-2 in I-girders with large D/b_f .

The full width of the widest compression flange within the field section under consideration is used for b_f in Eq. 6.10.11.1.2-2 to ensure a minimum stiffener width that will help restrain the widest compression flange. This requirement also conveniently allows for the use of the same minimum stiffener width throughout the entire field section, if desired. The widest top flange is used in Eq. 6.10.11.1.2-2 for tub sections since the bottom flange is restrained by a web along both of its edges. The limit of $b_f/4$ does not apply for closed box sections for the same reason.

of the widest top flange within the field section under consideration; for closed box sections, the limit of $b_f/4$ does not apply (in.)
 t_p = thickness of the projecting stiffener element (in.)

6.10.11.1.3—Moment of Inertia

For transverse stiffeners adjacent to web panels not subject to post-buckling tension-field action, i.e., where neither panel supports a factored shear force, V_u , larger than the factored shear resistance, $\phi_v V_{crs}$, the moment of inertia, I_t , of the transverse stiffener shall satisfy the smaller of the following limits:

$$I_t \geq I_{t1} \quad (6.10.11.1.3-1)$$

and:

$$I_t \geq I_{t2} \quad (6.10.11.1.3-2)$$

in which:

$$I_{t1} = b t_w^3 J \quad (6.10.11.1.3-3)$$

$$I_{t2} = \frac{D^4 \rho_t^{1.3}}{40} \left(\frac{F_{yw}}{E} \right)^{1.5} \quad (6.10.11.1.3-4)$$

$$J = \frac{2.5}{(d_o/D)^2} - 2.0 \geq 0.5 \quad (6.10.11.1.3-5)$$

$$F_{crs} = \frac{0.31E}{\left(\frac{b_t}{t_p} \right)^2} \leq F_{ys} \quad (6.10.11.1.3-6)$$

where:

I_t = moment of inertia of the transverse stiffener taken about the edge in contact with the web for single stiffeners and about the mid-thickness of the web for stiffener pairs (in.⁴)
 b = the smaller of d_o and D (in.)
 d_o = the smaller of the adjacent web panel widths (in.)
 J = transverse stiffener bending rigidity parameter
 ρ_t = the larger of F_{yw}/F_{crs} and 1.0
 F_{crs} = local buckling stress for the stiffener (ksi)
 F_{ys} = specified minimum yield strength of the stiffener (ksi)
 b_t = projecting width of the transverse stiffener (in.)
 F_{yw} = specified minimum yield strength of the web (ksi)

C6.10.11.1.3

For the web to adequately develop the shear buckling resistance or the combined shear buckling and post-buckling tension-field resistance as determined in Article 6.10.9, the transverse stiffener must have sufficient rigidity to maintain a vertical line of near zero lateral deflection along the line of the stiffener. For ratios of (d_o/D) less than 1.0, much larger values of I_t are required to develop the shear buckling resistance, as discussed in Bleich (1952) and represented by Eq. 6.10.11.1.3-1. For single stiffeners, a significant portion of the web is implicitly assumed to contribute to the bending rigidity such that the neutral axis of the stiffener is located close to the edge in contact with the web. Therefore, for simplicity, the neutral axis is assumed to be located at this edge and the contribution of the web to the moment of inertia about this axis is neglected. The use of the term b in Eq. 6.10.11.1.3-3 along with the term J from Eq. 6.10.11.1.3-5 give a constant value for the I_t required in Eq. 6.10.11.1.3-1 to develop the shear buckling resistance for web panels with $d_o > D$ (Kim and White, 2014).

Eq. 6.10.11.1.3-1 requires excessively large stiffener sizes as D/t_w is reduced below $1.12\sqrt{Ek/F_{yw}}$, the web slenderness required for $C = 1$, since Eq. 6.10.11.1.3-1 is based on developing the web elastic shear buckling resistance. Inelastic buckling solutions using procedures from Bleich (1952) show that larger stiffeners are not required as D/t_w is reduced below this limit. These results are corroborated by refined finite-element analysis (FEA) solutions (Kim and White, 2014). k is the shear buckling coefficient defined in Article 6.10.9.

To develop the web shear post-buckling resistance associated with tension-field action, the transverse stiffeners generally must have a larger I_t than defined by Eq. 6.10.11.1.3-1. The I_t defined by Eq. 6.10.11.1.3-2, which for $\rho_t = 1$ is approximately equal to the value required by Eq. 6.10.11.1.3-1 for a web with $D/t_w = 1.12\sqrt{Ek/F_{yw}}$, provides an accurate to slightly conservative stiffener size relative to refined FEA solutions for straight and curved I-girders at all values of D/t_w permitted by these Specifications (Kim and White, 2014). Eq. 6.10.11.1.3-2 is an approximate upper bound to the results for all values of d_o/D from an equation recommended by Kim and White (2014) recognizing that the stiffener demands are insensitive to this parameter.

Eq. 6.10.11.1.3-2 recognizes the fact that single- and double-sided transverse stiffeners with the same I_t exhibit essentially identical performance (Horne and Grayson, 1983) (Rahal and Harding, 1990) (Stanway et al., 1996) (Lee et al., 2003) (Kim and White, 2014).

- I_{t1} = minimum moment of inertia of the transverse stiffener required for the development of the web shear buckling resistance (in.⁴)
- I_{t2} = minimum moment of inertia of the transverse stiffener required for the development of the full web shear buckling plus post-buckling tension-field action resistance (in.⁴)
- t_p = thickness of the projecting stiffener element (in.)

For transverse stiffeners adjacent to web panels subject to post-buckling tension-field action, i.e., where one or both panels support a factored shear force, V_u , larger than the factored shear resistance, $\phi_v V_{cr}$, the moment of inertia, I_t , of the transverse stiffeners shall satisfy:

- If $I_{t2} > I_{t1}$, then:

$$I_t \geq I_{t1} + (I_{t2} - I_{t1}) \rho_w \quad (6.10.11.1.3-7)$$

- Otherwise:

$$I_t \geq I_{t2} \quad (6.10.11.1.3-8)$$

in which:

- If both web panels adjacent to the stiffener are subject to post-buckling tension-field action, then:

$$\rho_w = \text{maximum ratio of } \left(\frac{V_u - \phi_v V_{cr}}{\phi_v V_n - \phi_v V_{cr}} \right) \text{ within the two web panels}$$

- Otherwise:

$$\rho_w = \text{ratio of } \left(\frac{V_u - \phi_v V_{cr}}{\phi_v V_n - \phi_v V_{cr}} \right) \text{ within the one panel subject to post-buckling tension-field action}$$

$$\begin{aligned} V_{cr} &= \text{shear yielding or shear buckling resistance of the web panel under consideration (kip)} \\ &= CV_p \end{aligned} \quad (6.10.11.1.3-9)$$

$$\begin{aligned} V_p &= \text{plastic shear force (kip)} \\ &= 0.58 F_{yw} D t_w \end{aligned} \quad (6.10.11.1.3-10)$$

where:

- ϕ_v = resistance factor for shear specified in Article 6.5.4.2
- C = ratio of the shear buckling resistance to the shear yield strength determined by Eq. 6.10.9.3.2-4, 6.10.9.3.2-5, or 6.10.9.3.2-6, as applicable, with the shear buckling coefficient, k , taken equal to

The term, ρ_t , in Eq. 6.10.11.1.3-2 accounts conservatively for the effect of early yielding in transverse stiffeners with $F_{ys} < F_{yw}$ and for the effect of potential local buckling of stiffeners having a relatively large width-to-thickness ratio b/t_p . The definition of the stiffener local buckling stress, F_{crs} , is retained from AASHTO (1998).

Eq. 6.10.11.1.3-7 accounts for the fact that the I_t necessary to develop a shear resistance greater than or equal to V_u is smaller when V_u is smaller than the full factored combined web shear buckling and post-buckling resistance, $\phi_v V_n$ (Kim and White, 2014). For large girder depths, the philosophy of providing a stiffener flexural rigidity sufficient to develop $V_u = \phi_v V_n$ leads to stiffener sizes that are significantly larger than typically selected using prior AASHTO Specifications, where the former area requirement for the stiffeners was reduced when V_u was less than $\phi_v V_n$. Eq. 6.10.11.1.3-7 allows the calculation of a conservative but more economical stiffener size for these larger girder depths sufficient to develop a girder shear resistance greater than or equal to V_u . Eq. 6.10.11.1.3-8 addresses a small number of cases with stocky webs where V_n is approximately equal to V_p .

Multiple research studies have shown that transverse stiffeners in I-girders designed for tension-field action are loaded predominantly in bending due to the restraint they provide to lateral deflection of the web. Generally, there is evidence of some axial compression in the transverse stiffeners due to the tension field, but even in the most slender web plates permitted by these Specifications, the effect of the axial compression transmitted from the post-buckled web plate is typically minor compared to the lateral loading effect. Therefore, a transverse stiffener area requirement is not specified.

- 5 for unstiffened web panels and with k taken from Eq. 6.10.9.3.2-7 for stiffened web panels
- V_n = nominal shear yielding or shear buckling plus post-buckling tension-field action resistance of the web panel under consideration determined as specified in Article 6.10.9.3.2 (kip)
- V_u = maximum shear due to the factored loads in the web panel under consideration (kip)

Transverse stiffeners used in web panels with longitudinal stiffeners shall also satisfy:

$$I_t \geq \left(\frac{b_t}{b_\ell} \right) \left(\frac{D}{3.0d_o} \right) I_\ell \quad (6.10.11.1.3-11)$$

where:

- b_t = projecting width of the transverse stiffener (in.)
- b_ℓ = projecting width of the longitudinal stiffener (in.)
- I_ℓ = moment of inertia of the longitudinal stiffener determined as specified in Article 6.10.11.3.3 (in.⁴)

6.10.11.2—Bearing Stiffeners

6.10.11.2.1—General

Bearing stiffeners shall be placed on the webs of built-up sections at all bearing locations. At bearing locations on rolled shapes and at other locations on built-up sections or rolled shapes subjected to concentrated loads, where the loads are not transmitted through a deck or deck system, either bearing stiffeners shall be provided or the web shall satisfy the provisions of Article D6.5.

Except as specified herein, bearing stiffeners shall consist of one or more plates or angles welded or bolted to both sides of the web. Bearing stiffeners for I-girders may alternatively consist of half-round bearing stiffeners welded to both sides of the web. The connections to the web shall be designed to transmit the full bearing force due to the factored loads.

The stiffeners shall extend the full depth of the web and as closely as practical to the outer edges of the flanges.

Each stiffener should be finished to bear against the flange through which it receives its load. Plate and angle bearing stiffeners serving as connection plates shall be attached to both flanges of the cross-section as specified in Article 6.6.1.3.1. Half-round bearing stiffeners shall be fillet-welded to both flanges of the cross-section; all welds should be continuous to seal the interior of the half-round stiffeners. Connection plates shall be fillet-welded to half-round bearing stiffeners and should not be attached to the flanges of the cross-section.

Lateral loads along the length of a longitudinal stiffener are transferred to the adjacent transverse stiffeners as concentrated reactions (Cooper, 1967). Eq. 6.10.11.1.3-11 gives a relationship between the moments of inertia of the longitudinal and transverse stiffeners to ensure that the latter does not fail under the concentrated reactions. This equation applies whether the stiffeners are on the same or opposite side of the web.

C6.10.11.2.1

Webs of built-up sections and rolled shapes without bearing stiffeners at the indicated locations must be investigated for the limit states of web local yielding and web crippling according to the procedures specified in Article D6.5. The section should either be modified to comply with these requirements or else bearing stiffeners designed according to these Specifications should be placed on the web at the location under consideration.

In particular, inadequate provisions to resist temporary concentrated loads during construction that are not transmitted through a deck or deck system can result in failures. The Engineer should be especially cognizant of this issue when girders are incrementally launched over supports.

Half-round bearing stiffeners on I-girders allow for a perpendicular connection between the stiffener and a cross-frame or diaphragm connection plate for any skew angle at a support (Quadrato et al., 2010) and can also provide increased warping torsional restraint for LTB at the ends of unbraced lengths containing such stiffeners as discussed further in Articles C6.10.8.2.3a and CA6.3.3.1. Half-round bearing stiffeners are typically fabricated by splitting a pipe but can also be fabricated from plate. Fillet welds used to attach and seal half-round bearing stiffeners fabricated from plate and to attach connection plates to the half-round bearing stiffeners may be made according to the requirements of the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*. Fillet welds used to attach and seal

half-round bearing stiffeners fabricated by splitting a pipe should be made according to the requirements of the AWS D1.1/D1.1M *Structural Welding Code—Steel*. Corrosion due to any moisture trapped in the half-round during fabrication or any accumulated condensation inside the half-round is not possible in the absence of oxygen once the pipe is sealed by welding; once the oxygen is consumed, any corrosion will stop (Tournay, 2003). Half-round bearing stiffeners should not be used in galvanized structures since the vent holes required to prevent rupture from the expansion of the trapped air during galvanizing will allow the cleaning solutions to be trapped in the stiffener resulting in subsequent corrosion.

The use of full penetration groove welds to attach each stiffener to the flange though which it receives its load is permitted, but is not recommended in order to significantly reduce the welding deformation of the flange.

6.10.11.2.2—Minimum Thickness

The thickness, t_p , of each projecting plate stiffener element shall satisfy:

$$t_p \geq \frac{b_t}{0.48 \sqrt{\frac{E}{F_{ys}}}} \quad (6.10.11.2.2-1)$$

where:

F_{ys} = specified minimum yield strength of the stiffener (ksi)

b_t = width of the projecting plate stiffener element (in.)

The thickness, t , of half-round bearing stiffeners on I-girders shall satisfy:

$$t \geq \frac{18.2rF_{ys}}{E} \geq 0.375 \quad (6.10.11.2.2-2)$$

where:

r = outside radius of the half-round (in.)

6.10.11.2.3—Bearing Resistance

The factored bearing resistance for the fitted ends of bearing stiffeners shall be taken as:

$$(R_{sb})_r = \phi_b (R_{sb})_n \quad (6.10.11.2.3-1)$$

in which:

$(R_{sb})_n$ = nominal bearing resistance for the fitted ends of bearing stiffeners (kip)

C6.10.11.2.2

The provisions specified in this Article are intended to prevent local buckling of bearing stiffener plates or half-round bearing stiffeners. Eq. 6.10.11.2.2-2 was derived by expressing the value of λ_r for circular tubes given in Table 6.9.4.2.1-1 in terms of the outside radius of a single half-round and rearranging to solve for the thickness, t . The calculated thickness is not to be less than 0.375 in.

C6.10.11.2.3

To bring bearing stiffener plates tight against the flanges, part of the stiffener must be clipped to clear the web-to-flange fillet weld. Thus, the area of direct bearing is less than the gross area of the stiffener. The bearing resistance is based on this bearing area and the yield strength of the stiffener.

The specified factored bearing resistance is approximately equivalent to the bearing strength given in AISC (2022b). The nominal bearing resistance given by Eq. 6.10.11.2.3-2 is reduced from the

$$= 1.4 A_{pn} F_{ys} \quad (6.10.11.2.3-2)$$

where:

- ϕ_b = resistance factor for bearing, specified in Article 6.5.4.2
 A_{pn} = area of the projecting elements of the stiffener outside of the web-to-flange fillet welds but not beyond the edge of the flange (in.²)
 F_{ys} = specified minimum yield strength of the stiffener (ksi)

6.10.11.2.4—Axial Resistance of Bearing Stiffeners

6.10.11.2.4a—General

The factored axial resistance, P_r , shall be determined as specified in Article 6.9.2.1 using the specified minimum yield strength of the stiffener, F_{ys} . The radius of gyration shall be computed about the mid-thickness of the web and the effective length shall be taken as $0.75D$, where D is the web depth.

6.10.11.2.4b—Effective Section

For stiffeners bolted to the web, the effective column section shall consist of the stiffener elements only.

Except as noted herein, for stiffeners welded to the web, a portion of the web shall be included as part of the effective column section. For stiffeners consisting of two plates welded to the web, the effective column section shall consist of the two stiffener elements, plus a centrally located strip of web extending not more than $9t_w$ on each side of the plate stiffeners. If more than one pair of plate stiffeners is used, the effective column section shall consist of all stiffener elements, plus a centrally located strip of web extending not more than $9t_w$ on each side of the outer projecting elements of the group. For half-round bearing stiffeners, the effective column section shall be taken as a closed section consisting of the stiffener elements only.

The strip of the web shall not be included in the effective section of plate stiffeners at interior supports of continuous-span hybrid members for which the specified minimum yield strength of the web is less than 70 percent of the specified minimum yield strength of the higher-strength flange.

If the specified minimum yield strength of the web is less than that of the stiffener plates, the strip of the web included in the effective section shall be reduced by the ratio F_{yw}/F_{ys} .

nominal bearing resistance of $1.8A_{pn}F_{ys}$ specified in AISC (2022b) to reflect the relative difference in the resistance factors for bearing given herein and in AISC (2022b).

C6.10.11.2.4a

The end restraint against column buckling provided by the flanges allows for the use of a reduced effective length. The specified minimum yield strength of the stiffener, F_{ys} , is to be used in the calculation of the axial resistance to account for the early yielding of the lower-strength stiffener.

C6.10.11.2.4b

A portion of the web is assumed to act in combination with the plate bearing stiffeners. This portion of the web is not included for the stated case at interior supports of continuous-span hybrid members with F_{yw} less than the specified value because of the amount of web yielding that may be expected due to longitudinal flexural stress in this particular case. At end supports of hybrid members, the web may be included regardless of the specified minimum yield strength of the web.

If more than one pair of plate bearing stiffeners is used, AASHTO/NSBA (2020) recommends that a minimum spacing of 8.0 in. or 1.5 times the plate width be provided between the stiffeners for welding access. If the stiffeners are skewed, the spacing should be measured from the closest edge of the plate and not necessarily from the intersection of the plate with the web; more space will be required than for stiffeners perpendicular to the web. It is recommended that the maximum spacing between the stiffeners not exceed $1.0\lambda_w \sqrt{E/F_{ys}}$ to prevent an effective width reduction on the web of the section between the stiffeners.

For unusual cases in which F_{ys} is larger than F_{yw} , the yielding of the lower-strength web is accounted for in the stiffener axial resistance by adjusting the width of the web strip included in the effective section by F_{yw}/F_{ys} .

6.10.11.3—Web Longitudinal Stiffeners

6.10.11.3.1—General

Where required, longitudinal stiffeners should consist of either a plate welded to one side of the web, or a bolted angle. Longitudinal stiffeners shall be located at a vertical position on the web such that Eq. 6.10.3.2.1-3 is satisfied when checking constructibility, Eq. 6.10.4.2.2-4 is satisfied at the service limit state, and all the appropriate design requirements are satisfied at the strength limit state.

Longitudinal stiffeners should be included in calculating the section properties of the member gross cross-section.

Longitudinal stiffeners should be placed on the side of the web with the fewest transverse intermediate stiffeners and connection plates. Except as specified herein, at the intersection of a welded longitudinal stiffener and a welded transverse intermediate stiffener or connection plate, the vertical stiffener shall be interrupted and attached to the continuous longitudinal stiffener with fillet welds on both sides of the vertical and longitudinal stiffeners as shown in Table 6.6.1.2.4-1. The welds shall satisfy the minimum size requirements specified in Table 6.13.3.4-1. At bearing stiffeners, the longitudinal stiffener should be interrupted and similarly attached to the continuous bearing stiffener as shown in Table 6.6.1.2.4-1. Where more than one pair of bearing stiffeners is used, the longitudinal stiffener shall not be continued in-between the stiffener pair. The longitudinal stiffener may be similarly interrupted and attached to a continuous transverse intermediate stiffener or connection plate, but only at locations where the intersection is subject to a net compressive stress under Strength Load Combination I. The flexural stress in the longitudinal stiffener, f_s , due to the factored loads at the strength limit state and when checking constructability shall satisfy:

$$f_s \leq \phi_f R_h F_{ys} \quad (6.10.11.3.1-1)$$

where:

- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- F_{ys} = specified minimum yield strength of the stiffener (ksi)
- R_h = hybrid factor, determined as specified in Article 6.10.1.10.1

C6.10.11.3.1

For composite sections in regions of positive flexure, the depth of the web in compression D_c changes relative to the vertical position of a longitudinal web stiffener, which is usually a fixed distance from the compression flange, after the concrete deck has been placed. Thus, the computed web bend-buckling resistance is different before and after placement of the deck and is dependent on the loading. As a result, an investigation of several trial locations of the stiffener may be necessary to determine a location of the stiffener to satisfy Eq. 6.10.3.2.1-3 for constructibility, Eq. 6.10.4.2.2-4 at the service limit state, and the appropriate design requirements at the strength limit state along the girder. The following equation may be used to determine an initial trial stiffener location for composite sections in regions of positive flexure:

$$\frac{d_s}{D_c} = \frac{1}{1 + 1.5 \sqrt{\frac{f_{DC1} + f_{DC2} + f_{DW} + f_{LL+IM}}{f_{DC1}}}} \quad (C6.10.11.3.1-1)$$

where:

- d_s = distance from the centerline of a plate longitudinal stiffener, or the gauge line of an angle longitudinal stiffener, to the inner surface or leg of the compression flange element (in.)
- D_c = depth of the web of the noncomposite steel section in compression in the elastic range (in.)
- f_{xx} = compression flange stresses at the strength limit state caused by the different factored loads at the section with the maximum compressive flexural stress; i.e., $DC1$, the permanent load acting on the noncomposite section; $DC2$, the permanent load acting on the long-term composite section; DW , the wearing surface load; and $LL+IM$; acting on their respective sections (ksi). Flange lateral bending is to be disregarded in this calculation.

The stiffener may need to be moved vertically up or down from this initial trial location in order to satisfy all the specified limit-state criteria.

attached to the vertical web stiffeners as shown in Table 6.6.1.2.4-1. Longitudinal stiffeners should only be interrupted and left unattached to vertical web stiffeners if it is desired to terminate the longitudinal stiffener at that location, and either the location is subject to a net compressive stress or the nominal fatigue resistance of the longitudinal stiffener end detail is shown to be satisfactory should that location be subject to a net tensile stress determined as specified in Article 6.6.1.2.1. All stiffener intersections subject to a net tensile stress determined as specified in Article 6.6.1.2.1 must be designed with respect to fatigue. Copes or snipes should always be provided in the discontinuous element at the intersection to allow for continuous welds of the continuous element to the web.

For determining the nominal fatigue resistance of various longitudinal stiffener end details, refer to Condition 4.3 in Table 6.6.1.2.3-1. While the use of complete- or partial-penetration groove welds to attach the stiffener to the web or flange is permitted, the use of fillet welds is strongly encouraged as shown in Table 6.6.1.2.3-1. The use of groove welds does not enhance the nominal fatigue resistance of the end detail. Consideration should be given to wrapping the weld around the end of the stiffener for sealing. The weld and stiffener material should be ground to a smooth contour where the radiused stiffener end becomes tangent to the web or flange. Welded shop splices in longitudinal stiffeners should be complete-penetration groove-welded. Where longitudinal stiffeners are discontinued at bolted field splices, consideration should be given to taking the stiffener to the free edge of the web where the normal stress is zero.

Longitudinal stiffeners are subject to the same flexural strain as the web at their vertical position on the web. Therefore, they must have sufficient rigidity and strength to resist bend-buckling of the web, where required to do so, and to transmit the stresses in the stiffener and a portion of the web as an equivalent column (Cooper, 1967). Thus, full nominal yielding of the stiffeners is not permitted at the strength limit state and when checking constructibility as an upper bound. Eq. 6.10.11.3.1-1 serves as a limit on the validity of Eq. 6.10.11.3.3-2, which is in turn based on the axial resistance of an equivalent column section composed of the stiffener and a portion of the web plate. To account for the influence of web yielding on the longitudinal stiffener stress in hybrid members, the elastically computed stress in the stiffener is limited to $\phi_t R_h F_{ys}$ in Eq. 6.10.11.3.1-1. For the strength limit state and constructibility checks, the corresponding value of R_h at the section under consideration should be applied in Eq. 6.10.11.3.1-1.

6.10.11.3.2—Projecting Width

The projecting width, b_p , of the stiffener shall satisfy:

C6.10.11.3.2

This requirement is intended to prevent local buckling of the longitudinal stiffener.

$$b_f \leq 0.48t_s \sqrt{\frac{E}{F_{ys}}} \quad (6.10.11.3.2-1)$$

where:

t_s = thickness of the stiffener (in.)

6.10.11.3.3—Moment of Inertia and Radius of Gyration

C6.10.11.3.3

Longitudinal stiffeners shall satisfy:

$$I_{\ell} \geq D t_w^3 \left[2.4 \left(\frac{d_o}{D} \right)^2 - 0.13 \right] \beta \quad (6.10.11.3.3-1)$$

and:

$$r \geq \frac{0.16 d_o \sqrt{\frac{F_{ys}}{E}}}{\sqrt{1 - 0.6 \frac{F_{yc}}{R_h F_{ys}}}} \quad (6.10.11.3.3-2)$$

in which:

β = horizontal curvature correction factor for longitudinal stiffener rigidity calculated as follows:

- For cases where the longitudinal stiffener is on the side of the web away from the center of curvature:

$$\beta = \frac{Z}{6} + 1 \quad (6.10.11.3.3-3)$$

- For cases where the longitudinal stiffener is on the side of the web toward the center of curvature:

$$\beta = \frac{Z}{12} + 1 \quad (6.10.11.3.3-4)$$

Z = horizontal curvature parameter:

$$= \frac{0.95 d_o^2}{R t_w} \leq 12 \quad (6.10.11.3.3-5)$$

where:

d_o = transverse stiffener spacing (in.)

I_{ℓ} = moment of inertia of the longitudinal stiffener including an effective width of the web equal to $18t_w$ taken about the neutral axis of the combined section (in.⁴). If F_{yw} is smaller than

Eq. 6.10.11.3.3-1 ensures that the stiffener will have adequate rigidity to maintain a horizontal line of near zero lateral deflection in the web panel when necessary to resist bend-buckling of the web (Ziemian, 2010). Eq. 6.10.11.3.3-2 ensures that the longitudinal stiffener acting in combination with an adjacent strip of the web will withstand the axial compressive stress without lateral buckling. The moment of inertia, I_{ℓ} , and radius of gyration, r , are taken about the neutral axis of an equivalent column cross-section composed of the stiffener and an adjacent strip of the web, as suggested by Cooper (1967). The specified procedure for calculation of I_{ℓ} and r is consistent with the horizontally curved I-girder provisions of AASHTO (2003) in the limit that the girder is straight. The effect of the web plate having a lower yield strength than that of the longitudinal stiffener is accommodated by adjusting the web strip that contributes to the effective column section by F_{yw}/F_{ys} in the calculation of the moment of inertia of the longitudinal stiffener.

The rigidity required of longitudinal stiffeners on curved webs is greater than the rigidity required on straight webs because of the tendency of curved webs to bow. The factor β in Eq. 6.10.11.3.3-1 is a simplification of the requirement in the Hanshin (1988) provisions for longitudinal stiffeners used on curved girders. For longitudinal stiffeners on straight webs, Eq. 6.10.11.3.3-5 leads to $\beta = 1.0$.

Eq. 6.10.11.3.3-2 is based on the model described by Cooper (1967), except that the possibility of different specified minimum yield strengths for the stiffener and compression flange is accommodated. Also, the influence of a hybrid web is approximated by including the hybrid factor, R_h , within this equation. This is necessary because in these cases, the longitudinal stiffener is subjected to larger stresses compared to its resistance as an equivalent column than in an equivalent homogeneous section.

Article 6.10.9.3.1 requires that the shear resistance of the web panel be determined based on the total web depth D . Therefore, no area requirement is given for the longitudinal stiffeners to anchor the tension field.

F_{ys} , the strip of the web included in the effective section shall be reduced by the ratio F_{yw}/F_{ys}

R = minimum girder radius in the panel (in.)

r = radius of gyration of the longitudinal stiffener including an effective width of the web equal to $18t_w$ taken about the neutral axis of the combined section (in.)

6.10.12—Cover Plates

6.10.12.1—General

The length of any cover plate, L_{cp} , in ft, added to a member shall satisfy:

$$L_{cp} \geq \frac{d}{6.0} + 3.0 \quad (6.10.12.1-1)$$

where:

d = total depth of the steel section (in.)

Partial-length welded cover plates shall not be used on flanges more than 0.8 in. thick for nonredundant load path structures subjected to repetitive loadings that produce tension or reversal of stress in the flange.

The maximum thickness of a single cover plate on a flange shall not be greater than two times the thickness of the flange to which the cover plate is attached. Multiple welded cover plates shall not be permitted.

Cover plates may either be wider or narrower than the flange to which they are attached.

6.10.12.2—End Requirements

6.10.12.2.1—General

The theoretical end of the cover plate shall be taken as the section where the moment, M_u , or flexural stress, f_{bu} , due to the factored loads equals the factored flexural resistance of the flange. The cover plate shall be extended beyond the theoretical end far enough so that:

- the stress range at the actual end satisfies the appropriate fatigue requirements specified in Article 6.6.1.2, and
- the longitudinal force in the cover plate due to the factored loads at the theoretical end can be developed by welds and/or bolts placed between the theoretical and actual ends.

The width at ends of tapered cover plates shall not be less than 3.0 in.

6.10.12.2.2—Welded Ends

The welds connecting the cover plate to the flange between the theoretical and actual ends shall be adequate to develop the computed force in the cover plate at the theoretical end.

Where cover plates are wider than the flange, welds shall not be wrapped around the ends of the cover plate.

6.10.12.2.3—Bolted Ends

The bolts in the slip-critical connections of the cover plate to the flange between the theoretical and actual ends shall be adequate to develop the force due to the factored loads in the cover plate at the theoretical end.

The slip resistance of the end-bolted connection shall be determined in accordance with Article 6.13.2.8. The longitudinal welds connecting the cover plate to the flange shall be continuous and shall stop a distance equal to one bolt spacing before the first row of bolts in the end-bolted portion. Where end-bolted cover plates are used, the contract documents shall specify that they be installed in the following sequence:

- drill holes,
- clean faying surfaces,
- install bolts, and
- weld plates.

6.11—COMPOSITE BOX-SECTION FLEXURAL MEMBERS

6.11.1—General

The provisions of this Article apply to flexure of straight or horizontally curved composite steel single or multiple closed-box or tub sections in simple or continuous bridges of moderate length. The provisions cover the design of composite, hybrid and nonhybrid, and constant and variable web depth members as defined by and subject to the requirements of Article 6.10.1.1, Articles 6.10.1.3 through 6.10.1.8, and Articles 6.11.1.1 through 6.11.1.4. The provisions of Article 6.10.1.6 shall apply only to the top flanges of tub sections.

Single box sections shall be positioned in a central position with respect to the cross-section, and the center of gravity of the dead load shall be as close to the shear center of the box as is practical. These provisions shall not be applied to multiple-cell single box sections, or to composite box flanges used as bottom flanges.

All types of composite box-section flexural members shall be designed as a minimum to satisfy:

- The cross-section proportion limits specified in Article 6.11.2;

C6.10.12.2.3

Research on end-bolted cover plates is discussed in Wattar et al. (1985).

C6.11.1

Article 6.11.1 addresses general topics that apply to composite closed-box and tub sections used as flexural members in either straight bridges, horizontally curved bridges, or bridges containing both straight and curved segments. For the application of the provisions of Article 6.11, bridges containing both straight and curved segments are to be treated as horizontally curved bridges since the effects of curvature on the support reactions and girder deflections, as well as the effects of flange lateral bending and torsional shear, usually extend beyond the curved segments. The term moderate length as used herein refers to bridges of spans up to approximately 350 ft. The provisions may be applied to larger spans based on a thorough evaluation of the application of the bridge under consideration consistent with basic structural fundamentals. For a general overview on box-girder bridges, refer to Coletti et al. (2005).

The five bullet items in this Article indicate the overarching organization of the subsequent provisions for

- The constructibility requirements specified in Article 6.11.3;
- The service limit state requirements specified in Article 6.11.4;
- The fatigue and fracture limit state requirements specified in Article 6.11.5;
- The strength limit state requirements specified in Article 6.11.6.

The web bend-buckling resistance in slender web members shall be determined as specified in Article 6.10.1.9. Flange-strength reduction factors in hybrid and/or slender web members shall be determined as specified in Article 6.10.1.10.

Internal and external cross-frames and diaphragms for box sections shall satisfy the provisions of Article 6.7.4. Top-flange bracing for tub sections shall satisfy the provisions of Article 6.7.5.

the design of box-section flexural members. To avoid repetition, some of the general topics in this Article refer back to the general provisions of Article 6.10.1 for I-sections, which apply equally well to box sections. Where necessary, other Articles in Article 6.10 are referred to at appropriate points within Article 6.11.

Within these provisions, the term box flange refers to a flange plate connected to two webs.

These provisions do not apply to the use of box sections which are noncomposite in the final condition, as defined in Article 6.10.1.2, as flexural members. Such members are covered by the provisions of Article 6.12.2.2.2. The concrete deck is to be assumed effective over the entire span length in the analysis for loads applied to the composite section according to the provisions of Article 6.10.1.5. Therefore, shear connectors must be present along the entire span to resist the torsional shear that exists along the entire span in all types of composite box sections in order to avoid possible debonding of the deck. Shear connectors must also be present in regions of negative flexure in order to be consistent with the prototype and model bridges that were studied in the original development of the live-load distribution provisions for box sections (Johnston and Mattock, 1967). For considerations while a composite box section is under construction, applicable provisions of Articles 6.10 and 6.11 may be utilized depending on whether the section is thought to be effectively open or quasi-box in behavior, respectively. The flexural resistance of noncomposite closed-box sections used as compression or tension members is specified in Article 6.12.2.2.2.

These provisions may be applied to the use of composite closed-box sections, or sections utilizing a steel plate for the top flange that is composite with the concrete deck, as flexural members. The use of such sections has been relatively rare in the U.S. to date due to cost considerations related to the implementation of necessary safety requirements for working inside of closed boxes. These Specifications do not apply to the use of composite concrete on bottom box flanges in order to stiffen the flanges in regions of negative flexure.

The use of single box sections is permitted in these Specifications because torsional equilibrium can be established with two bearings at some supports. Placing the center of gravity of the dead load near the shear center of single box sections ensures minimal torsion. Items such as sound barriers on one side of the bridge may be critical on single box sections.

These Specifications do not apply to multiple-cell single box sections because there has been little published research in the U.S. regarding these members. Analysis of this bridge type involves consideration of shear flow in each cell.

In variable web depth box members with inclined webs, the inclination of the webs should preferably remain constant in order to simplify the analysis and the fabrication. For a constant distance between the webs at the top of the box, which is also preferred, this requires that the width of the bottom flange vary along the length

and that the web heights at a given cross-section be kept equal. If the bridge is to incrementally launched, a constant depth box is recommended.

The provisions of Article 6.11 provide a unified approach for consideration of combined major-axis bending and flange lateral bending from any source in the design of top flanges of tub sections during construction. These provisions also provide a unified approach for consideration of the combined effects of normal stress and St. Venant torsional shear stress in closed-box and tub sections both during construction and in the final constructed condition. General design equations are provided for determining the nominal flexural resistance of box flanges under the combined effects of normal stress and torsional shear stress. The provisions also allow for the consideration of torsional shear in the design of the box-section webs and shear connectors. For straight boxes, the effects of torsional shear are typically relatively small unless the bridge is subjected to large torques. For example, boxes resting on skewed supports are usually subjected to large torques. For horizontally curved boxes, flange lateral bending effects due to curvature and the effects of torsional shear must always be considered at all limit states and also during construction.

For cases where the effects of the flange lateral bending and/or torsional shear are judged to be insignificant or incidental, or are not to be considered, the terms related to these effects are simply set equal to zero in the appropriate equations. Fundamental calculations for flexural members have been placed in Appendix D6.

6.11.1.1—Stress Determinations

Box flanges in multiple and single box sections shall be considered fully effective in resisting flexure if the width of the flange does not exceed one-fifth of the effective span. For simple spans, the effective span shall be taken as the span length. For continuous spans, the effective span shall be taken equal to the distance between points of permanent load contraflexure, or between a simple support and a point of permanent load contraflexure, as applicable. If the flange width exceeds one-fifth of the effective span, a gross width equal to one-fifth of the effective span shall be considered in resisting flexure to account for shear lag effects. The reduced gross width of the box flange, accounting for shear lag, shall be employed in calculating the flexural stresses in the box section, and in calculating the nominal flexural resistance of the section in the case of compact sections in positive flexure. The reductions shall not be applied within the bridge structural analysis.

For multiple box sections in straight bridges satisfying the requirements of Article 6.11.2.3, the live-load flexural moment in each box may be determined in accordance with the applicable provisions of Article 4.6.2.2.2b. Shear due to St. Venant torsion and

C6.11.1.1

Stress analyses of actual box girder bridge designs were carried out to evaluate the effective width of a box flange using a series of folded plate equations (Goldberg and Leve, 1957). Bridges for which the span-to-flange width ratio varied from 5.65 to 35.3 were included in the study. The effective flange width as a ratio of the total flange width covered a range from 0.89 for the bridge with the smallest span-to-width ratio to 0.99 for the bridge with the largest span-to-width ratio. On this basis, it is reasonable to permit a box flange to be considered fully effective and subject to a uniform longitudinal stress, provided that its width does not exceed one-fifth of the span of the bridge. For extremely wide box flanges, a special investigation for shear lag effects may be required.

Although the results quoted above were obtained for simply supported bridges, this criterion would apply equally to continuous bridges using the appropriate effective span defined in this Article for the section under consideration.

For extreme cases in which the box flange width exceeds one-fifth of the effective span, increased box-section flexural stresses are calculated by using a reduced

transverse bending and longitudinal warping stresses due to cross-section distortion may also be neglected for sections within these bridges that have fully effective box flanges. The section of an exterior member assumed to resist horizontal factored wind loading within these bridges may be taken as the bottom box flange acting as a web and 12 times the thickness of the web acting as flanges.

The provisions of Article 4.6.2.2.2b shall not apply to:

- Single box sections in straight or horizontally curved bridges,
- Multiple box sections in straight bridges not satisfying the requirements of Article 6.11.2.3, or
- Multiple box sections in horizontally curved bridges.

For these sections, and for sections that do not have fully effective box flanges, the effects of both flexural and St. Venant torsional shear shall be considered. The St. Venant torsional shear stress in box flanges due to the factored loads at the strength limit state shall not exceed the factored torsional shear resistance of the flange, F_{vr} , taken as:

$$F_{vr} = 0.75\phi_v \frac{F_{yf}}{\sqrt{3}} \quad (6.11.1.1-1)$$

where:

ϕ_v = resistance factor for shear, specified in Article 6.5.4.2

In addition, transverse bending stresses due to cross-section distortion shall be considered for fatigue as specified in Article 6.11.5, and at the strength limit state. Transverse bending stresses due to the factored loads shall not exceed 20.0 ksi at the strength limit state. Longitudinal warping stresses due to cross-section distortion shall be considered for fatigue as specified in Article 6.11.5, but may be ignored at the strength limit state. Transverse bending and longitudinal warping stresses shall be determined by rational structural analysis in conjunction with the application of strength-of-materials principles. Transverse stiffeners attached to the webs or box flanges should be considered effective in resisting transverse bending.

gross width of the box flange. In addition, the nominal flexural resistance of compact sections in positive flexure is reduced by using the reduced gross width of the box flange. Box-flange effective width reductions accounting for plate post-buckling effects due to compression at the strength limit state are independent from the reductions due to shear lag effects. The effective width reductions due to plate post-buckling effects are defined in Article 6.11.8.2.2b, and are accounted for separately via reduction factors that are applied to the box-flange flexural resistance. These reductions are relative to the gross cross-section without considering shear lag effects. This separate handling of shear lag effects under all loadings, and plate post-buckling effects under factored strength loadings, simplifies the consideration of these separate effects. Neither of these reductions are to be applied within the bridge structural analysis.

Closed-box sections are capable of resisting torsion with limited distortion of the cross-section. Since distortion is generally limited by providing sufficient internal bracing in accordance with Article 6.7.4.3, torsion is resisted mainly by St. Venant torsional shear flow. The warping constant for closed-box sections is approximately equal to zero. Thus, warping shear and normal stresses due to warping torsion are typically quite small and are usually neglected.

Transverse bending stresses in box flanges and webs due to distortion of the box cross-section occur due to changes in direction of the shear flow vector. The transverse bending stiffness of the webs and flanges alone is not sufficient to retain the box shape so internal cross-bracing is required. Longitudinal warping stresses due to cross-section distortion are also best controlled by internal cross-bracing, as discussed further in Article C6.7.4.3.

Top flanges of tub girders subject to torsional loads need to be braced so that the section acts as a pseudo-box for noncomposite loads applied before the concrete deck hardens or is made composite. Top-flange bracing working with internal cross-bracing retains the box shape and resists lateral force induced by inclined webs and torsion.

As discussed further in Article C6.11.2.3, for multiple box sections in straight bridges that conform to the restrictions specified in Article 6.11.2.3, the effects of St. Venant torsional shear and secondary distortional stresses may be neglected unless the box flange is very wide. The live-load distribution factor specified in Article 4.6.2.2.2b for straight multiple steel box sections may also be applied in the analysis of these bridges. Bridges not satisfying one or more of these restrictions must be investigated using one of the available methods of refined structural analysis, or other acceptable methods of approximate structural analysis as specified in Articles 4.4 or 4.6.2.2.4, since the specified live-load distribution factor does not apply to such bridges. The effects of St. Venant torsional shear and secondary distortional stresses are

also more significant and must therefore be considered for sections in these bridges. Included in this category are all types of bridges containing single box sections, and horizontally curved bridges containing multiple box sections. Transverse bending stresses are of particular concern in boxes that may be subjected to large torques; e.g., single box sections, sharply curved boxes, and boxes resting on skewed supports. For other cases, the distortional stresses may be ignored if it can be demonstrated that the torques are of comparable magnitude to the torques for cases in which research has shown that these stresses are small enough to be neglected (Johnston and Mattock, 1967), e.g., a straight bridge of similar proportion satisfying the requirements of Article 6.11.2.3 or if the torques are deemed small enough in the judgment of the Owner and the Engineer. In such cases, it is recommended that all web stiffeners be attached to both flanges to enhance fatigue performance.

In single box sections in particular, significant torsional loads may occur during construction and under live loads. Live loads at the extreme of the deck can cause critical torsional loads without causing critical flexural moments. In the analysis, live load positioning should be done for flexure and torsion. The position of the bearings should be recognized in the analysis in sufficient completeness to permit direct computation of the reactions.

Where required, the St. Venant torsional shear and shear stress in web and flange elements can be calculated from the shear flow, which is determined as follows:

$$f = \frac{T}{2A_o} \quad (\text{C6.11.1.1-1})$$

where:

- A_o = enclosed area within the box section (in.²)
- f = shear flow (kip/in.)
- T = factored internal torque (kip-in.)

For torques applied to the noncomposite section, A_o is to be computed for the noncomposite box section. As specified in Article 6.7.5.3, if top lateral bracing in a tub section is attached to the webs, A_o is to be reduced to reflect the actual location of the bracing. Because shear connectors are required along the entire length of box sections according to these provisions, the concrete deck can be considered effective in resisting torsion at any point along the span. Therefore, for torques applied to the composite section in regions of positive or negative flexure, A_o is to be computed for the composite section using the depth from the bottom flange to the mid-thickness of the concrete deck. The depth may be computed using a lower-bound estimate of the actual thickness of the concrete haunch, or may be determined conservatively by neglecting the thickness of the haunch.

The torsion acting on the composite section also introduces horizontal shear in the concrete deck that should be considered when designing the reinforcing steel. Article C6.11.10 suggests a procedure for determining the torsional shear in the concrete deck for closed-box sections. For tub sections, the deck should be assumed to resist all the torsional shear acting on top of the composite box section.

Previous editions of AASHTO's *Guide Specifications for Horizontally Curved Highway Bridges* (AASHTO, 1993) limited the nominal St. Venant torsional shear resistance of box flanges to the shear yield stress, $F_{yf}/\sqrt{3}$. However, at this level of shear stress, there is a significant reduction in the nominal flexural resistance of the flange. Therefore, the nominal shear resistance is limited to $0.75 F_{yf}/\sqrt{3}$ in these provisions. Such a level of torsional shear stress is rarely, if ever, encountered in practical box-girder designs.

Where required, transverse or through-thickness bending stresses and stress ranges in the webs and flanges due to cross-section distortion can be determined using the beam-on-elastic-foundation (BEF) analogy presented by Wright and Abdel-Samad (1968a). In this method, the internal diaphragms or cross-frames are analogous to intermediate supports in the BEF, and the resistance to distortion provided by the box cross-section is analogous to a continuous elastic foundation. The deflection of the BEF is analogous to the transverse bending stress. Transverse stiffeners should be considered effective with the web or box flange, as applicable, in computing the flexural rigidities of these elements. Sample calculations based on the BEF analogy are presented in Heins and Hall (1981) and in AASHTO (2003). The use of finite-element analysis to determine through-thickness bending stresses as part of the overall analysis of box sections is impractical due to the mesh refinement necessary for the accurate calculation of these stresses.

Longitudinal warping stresses due to cross-section distortion can also be determined using the BEF analogy. The warping stress is analogous to the moment in the BEF. The warping stresses are largest at the corners of the box where critical welded details are often located and should be considered for fatigue (Wright and Abdel-Samad, 1968b). Tests have indicated that these warping stresses do not affect the ultimate strength of box girders of typical proportions.

Since top lateral bracing contributes to the flexural stiffness of tub sections, consideration should be given to including the longitudinal component of the top-flange bracing area when computing the section properties of the tub. Where used, flange longitudinal stiffeners should also be included in the section properties of the box or tub.

6.11.1.2—Bearings

Single or double bearings may be used at supports. Double bearings may be placed either inboard or

C6.11.1.2

The bearing arrangement dictates how torsion is resisted at supports and is especially critical for single box

outboard of the box section webs. If single bearings narrower than the bottom flange are used, they shall be aligned with the shear center of the box, and other supports shall have adequate bearings to ensure against overturning under any load combination. If tie-down bearings are used, the resulting force effects shall be considered in the design.

6.11.1.3—Flange-to-Web Connections

Except as specified herein, the total effective thickness of flange-to-web welds shall not be less than the smaller of the web or flange thickness.

Where two or more intermediate internal cross-frames or diaphragms are provided in each span, fillet welds may be used for the flange-to-web connections. The weld size shall not be less than the size consistent with the requirements of Article 6.13.3.4. If fillet welds are used, they shall be placed on both sides of the connecting flange or web plate.

6.11.1.4—Access and Drainage

Access holes in box sections should be located in the bottom flange in areas of low stress. The effect of access holes on the stresses in the flange should be investigated at all limit states to determine if reinforcement of the holes is required. At access holes in box flanges subject to compression, the nominal flexural resistance of the remaining flange on each side of the hole at the strength limit state shall be determined according to the provisions of Article 6.10.8.2.2, with λ_f taken as the projecting width of the flange on that side of the hole divided by the flange thickness, including any reinforcement. Provisions should be made for ventilation and drainage of the interior of box sections.

sections. When a single bearing arrangement is used, torque may be removed from multiple box sections through cross-frames or diaphragms between the boxes. Two bearings under each box provide a couple to resist the torque in each box. Double bearings can be placed between the box webs or outboard of the box. Placing bearings outboard of the box reduces overturning loads on the bearings and may eliminate uplift. For the case of double bearings, uplift may be especially critical when deck overhangs are large and heavy parapets or sound barriers are placed at the edges of the overhangs. Uplift should be checked ignoring the effect of the future wearing surface.

Integral cap beams of steel or concrete are often used with box sections in lieu of bearings.

C6.11.1.3

If at least two intermediate internal cross-frames or diaphragms are not provided in each span, it is essential that the web-to-flange welds be of sufficient size to develop the smaller of the full web or flange section. Full-thickness welds should be provided in this case because of the possibility of secondary flexural stresses developing in the box section as a result of vibrations and/or distortions of the cross-section. Haaijer (1981) demonstrates that the transverse secondary distortional stress range at the web-to-flange welded joint is reduced more than 50 percent in such sections when one intermediate internal cross-frame per span is introduced and more than 80 percent when two intermediate internal cross-frames per span are introduced. Thus, when two or more intermediate internal cross-frames or diaphragms are provided in each span, fillet welds on both sides of the web designed according to the requirements of Article 6.13.3.4 may be assumed to be adequate.

It is essential that the welds be placed on both sides of the connecting flange or web plate whether full penetration or fillet welds are used. This will help minimize the possibility of a fatigue failure resulting from the transverse bending stresses.

C6.11.1.4

At access holes in box flanges subject to compression, the nominal flexural resistance of the remaining flange on each side of the hole is determined using the local buckling resistance equations for I-girder compression flanges, with the flange slenderness based on the projecting width of the flange on that side of the hole.

Outside access holes should be large enough to provide easy access for inspection. Doors for exterior access holes should be hinged and provided with locks. All outside openings in box sections should be screened to exclude unauthorized persons, birds, and vermin.

Consideration should be given to painting the interior of box sections a light color. Painting the interior of these sections is primarily done to facilitate

inspections, and for tub sections, to prevent solar gain and to offer a minimum level of protection to the steel from the elements while the tub is temporarily open during construction. The paint quality need not match that normally used for exterior surfaces. A single-coat system should be sufficient in most cases, particularly when provisions are made for ventilation and drainage of the interior of the box.

6.11.2—Cross-Section Proportion Limits

6.11.2.1—Web Proportions

6.11.2.1.1—General

Webs may be inclined or vertical. The inclination of the web plates to a plane normal to the bottom flange shall not exceed 1 to 2.5. For the case of inclined webs, the distance along the web shall be used for checking all design requirements.

C6.11.2.1.1

Inclined webs are advantageous in reducing the width of the bottom flange. An outward inclination of the web plates to a plane normal to the bottom flange of one unit horizontally away from the plane to four units vertically along the plane is typically provided. However, shallower web inclinations with a limiting value of 1 unit horizontally away from the plane to 2.5 units vertically along the plane may be used, which can potentially reduce the number of girder lines as well as minimize the bottom flange width. Note that the shear demand on each web will increase with a shallower web inclination as will the demand on the top lateral struts connecting the top flanges resulting from the horizontal component of the web shear (Armijos-Moya et al., 2019).

Webs attached to top flanges of tub sections are typically positioned at mid-width of the flanges. An inward offset of the top flanges may be advantageous to efficiently connect the top-flange lateral bracing to the flanges (Armijos-Moya et al., 2019). When the top flanges are offset, the minimum projecting flange width outside the box section measured from the centerline of the web should be between 5.0 and 6.5 inches to accommodate girder lifting and handling. Bolted extension plates at the appropriate points along the outer edge of the top flanges can be used to provide more top-flange width and reduce the eccentric loading during lifting. When checking Eq. 6.11.2.2-1 and when calculating the FLB resistance specified in Article 6.10.8.2.2 during the deck placement, which will indirectly limit the maximum offset of the top flanges, $b_f/2t_f$ should be replaced with b_i/t_f , where b_i is the larger projecting flange width inside the box section measured from the centerline of the web. When calculating top-flange lateral bending stresses in this case, the lateral section modulus of each flange should be based upon the moment of inertia about the flange-to-web juncture and an extreme fiber distance equal to b_i since the axis of bending about the web has shifted from the mid-width of the flange (Wang, 2019). Armijos-Moya et al. (2019) also provide some suggested bolted top-flange splice details for use with offset top flanges.

6.11.2.1.2—Webs without Longitudinal Stiffeners**C6.11.2.1.2**

Webs shall be proportioned such that:

Eq. 6.11.2.1.2-1 is discussed in Article C6.10.2.1.1.

$$\frac{D}{t_w} \leq 150 \quad (6.11.2.1.2-1)$$

6.11.2.1.3—Webs with Longitudinal Stiffeners**C6.11.2.1.3**

Webs shall be proportioned such that:

Eq. 6.11.2.1.3-1 is discussed in Article C6.10.2.1.2.

$$\frac{D}{t_w} \leq 300 \quad (6.11.2.1.3-1)$$

6.11.2.2—Flange Proportions**C6.11.2.2**

Top flanges of tub sections subject to compression or tension shall be proportioned such that:

Eqs. 6.11.2.2-1 through 6.11.2.2-3 apply to flanges of I-sections and are also applied to a single top flange of a tub section. Eqs. 6.11.2.2-1 through 6.11.2.2-3 are discussed in Article C6.10.2.2. Eq. 6.11.2.2-3 is intended only for application to built-up tub-section members utilizing different size flange and web plates and need not be applied to tub-section members that are fabricated from a single plate. A parametric analytical assessment of tub-section members fabricated from a single plate found that all local and distortional buckling modes occurred well above M_y ; therefore, local buckling is not an issue for the web and the top compression flanges when assessing the stability of these members (Barth and Michaelson, 2018).

$$\frac{b_f}{2t_f} \leq 12.0, \quad (6.11.2.2-1)$$

$$b_f \geq D/6, \quad (6.11.2.2-2)$$

and:

$$t_f \geq 1.1t_w \quad (6.11.2.2-3)$$

where:

b_f = width of the single top flange under consideration (in.)

D = web depth taken as the depth of the web plate measured along the slope for cases with inclined webs (in.)

t_f = thickness of the single top flange under consideration (in.)

t_w = web thickness (in.)

Eq. 6.11.2.2-3 shall apply only to built-up tub-section members.

Longitudinally unstiffened box flanges subject to compression or tension should be proportioned such that:

$$b_{fi}/t_f \leq 90 \quad (6.11.2.2-4)$$

where:

b_{fi} = clear width of the box flange under consideration between the webs (in.)

t_f = thickness of the box flange under consideration (in.)

Box flanges subject to compression and exceeding the limit given by Eq. 6.11.2.2-4 shall include longitudinal stiffeners. In addition, box flanges subject

Noncomposite box flanges, i.e., box flanges that are not attached to a concrete deck slab, subjected to compression will tend to be limited to b_{fi}/t_f significantly less than 90 or w/t_f less than 90, as applicable, by the provisions of Articles 6.11.3.2 and 6.11.4 during construction and at the service limit state, respectively. Refer to Figure CE6.1.3-1 for further information on the definition of the variable, w , for longitudinally stiffened box flanges.

The limits of $b_{fi}/t_f \leq 90$, $w/t_f \leq 90$, and $t_f \geq 0.5$ in. are recommended to limit potential local deformation or distortion of noncomposite box flanges during fabrication, transportation, erection, and service conditions. Flanges violating these limits may have out-of-plane plate deflections approaching a significant fraction of $b_{fi}/300$ or $w/300$ under their self-weight plus a transverse concentrated load of 300 lbs., which is considered by ASCE 7-16 (ASCE, 2016) as a visible deflection limit. These limits also help alleviate significant buckling distortion due to welding residual stresses resulting in oil canning and waviness of the flange, and the amplification of these distortions by small unintended axial compressive and/or shear stresses under service conditions, such as shifting of true inflection point locations from nominal positions calculated in the design (White et al., 2019a).

only to tension and with b_{fl}/t_f exceeding 130 shall include longitudinal stiffeners. Longitudinally stiffened box flanges should be proportioned such that:

$$w/t_f \leq 90 \quad (6.11.2.2-5)$$

where:

w = width of the box-flange plate between the centerlines of the individual longitudinal stiffeners and/or between the centerline of a longitudinal stiffener and the inside of the laterally restrained longitudinal edge of the longitudinally stiffened plate element under consideration, as applicable (in.)

The thickness of box flanges subject to compression or tension shall not be less than 0.5 in., unless otherwise specified by the Owner, and should not be less than the thickness of the webs.

Flange extensions on box flanges subject to compression shall be proportioned such that:

$$b/t_f \leq 0.38 \sqrt{\frac{E}{F_y}} \quad (6.11.2.2-6)$$

where:

b = clear projecting width of the box flange under consideration measured from the outside surface of the web (in.)

t_f = thickness of the box flange under consideration (in.)

For box flanges with b_{fl}/t_f or w/t_f greater than 100, some noticeable buckling distortion of the flange plate may occur during fabrication due to minimal welding of the flange plate to the webs and/or welding of any stiffeners to the flange plate. In addition, the nominal resistance of compression flanges is relatively small when b_{fl}/t_f or w/t_f exceeds 100. Box flanges with b_{fl}/t_f or w/t_f values larger than about 130 will have difficulty satisfying the $b_{fl}/300$ or $w/300$ out-of-plane deflection limits under self-weight, or under self-weight with a small concentrated transverse load; therefore, plate out-of-plane sagging due to these nominal loads may be noticeable.

The thickness of a box flange should not be smaller than the web thickness. As such, the plate bending stresses due to distortion of the box section under torsional loads will tend to be larger in the webs than in the box flange.

A minimum thickness of 0.75 in. is recommended for box flanges. This suggested minimum thickness is intended to ensure robustness and resiliency of the member response, to facilitate handling, and to minimize distortion and possible cupping of the plates during welding. An absolute minimum thickness of 0.5 in. is specified, unless otherwise permitted by the Owner, to avoid increasing sensitivity to welding distortions and deflections under self-weight and small concentrated applied loads.

Box flanges should extend at least one inch beyond the outside of each web to allow for welding of the webs to the flange. The Engineer should consider providing an option on the design plans for the fabricator to increase this distance, if necessary, to provide for greater welding access. Eq. 6.11.2.2-6 limits the width-to-thickness ratio of extensions in box flanges subject to compression such that these components are not subject to any strength reduction associated with local buckling under flexural compression. As such, the full gross width of the extensions, measured from the outside surface of the box section webs, may be employed in the calculation of the effective and gross box-section properties.

6.11.2.3—Special Restrictions on Use of Live Load Distribution Factor for Multiple Box Sections

Cross-sections of straight bridges consisting of two or more single-cell box sections, for which the live load flexural moment in each box is determined in accordance with the applicable provisions of Article 4.6.2.2.2b, shall satisfy the geometric restrictions specified herein. In addition, the bearing lines shall not be skewed.

The distance center-to-center of flanges of adjacent boxes, a , taken at the midspan, shall neither be greater than 120 percent nor less than 80 percent of the distance center-to-center of the flanges of each adjacent box, w , as illustrated in Figure 6.11.2.3-1. In addition to the midspan requirement, where nonparallel box sections are used, the

C6.11.2.3

Restrictions specified in this Article for straight bridges utilizing multiple box sections are necessary in order to employ the lateral live-load distribution factor given in Article 4.6.2.2.2b for straight multiple steel box sections. The development of this distribution factor is based on an extensive study of bridges that conform to these limitations (Johnston and Mattock, 1967). The study assumed an uncracked stiffness for the composite section along the entire span.

Further, it was determined that when these restrictions are satisfied, shear due to St. Venant torsion and secondary distortional bending stress effects may be

distance center-to-center of adjacent flanges at supports shall neither be greater than 135 percent nor less than 65 percent of the distance center-to-center of the flanges of each adjacent box. The distance center-to-center of flanges of each individual box shall be the same.

The cantilever overhang of the concrete deck, including curb and parapet, shall not be greater than either 60 percent of the average distance between the centers of the top steel flanges of adjacent box sections, a , or 6.0 ft.

Figure 6.11.2.3-1—Center-to-Center Flange Distance

neglected if the width of the box flange does not exceed one-fifth of the effective span defined in Article 6.11.1.1. It was found from an analytical study of bridges of this type that when such bridges were loaded so as to produce maximum moment in a particular girder, and hence maximum compression in the flange plate near an intermediate support, the amount of twist in that girder was negligible. It therefore appears reasonable that, for bridges conforming to the restrictions set forth in this Article and with fully effective box flanges, shear due to torsion need not be considered in the design of box flanges for maximum compression or tension loads.

In the case of bridges with support skew, additional torsional effects occur in the box sections and the lateral distribution of loads is also affected. Although the bridge may satisfy the cross-section restrictions of this Article, these effects are not comprehended by the lateral distribution factor specified in Article 4.6.2.2.2b. Therefore, in these cases, a more rigorous analysis of stresses is necessary using one of the available methods of refined structural analysis. For straight portions of bridges that satisfy these restrictions, but that also contain horizontally curved segments, a refined analysis is also recommended. Although not required, refined structural analysis methods may also be used for bridges satisfying the restrictions of this Article, if desired.

Some limitations are placed on the variation of the distance a with respect to the distance w shown in Figure 6.11.2.3-1 when the distribution factor is used because the studies on which the live load distribution provisions are based were made on bridges in which a and w were equal. The limitations given for nonparallel box sections will allow some flexibility of layout in design while generally maintaining the validity of the provisions. For cases with nonparallel box sections where the live load distribution factor is employed, refer to the provisions of Article 4.6.2.2.2b.

6.11.3—Constructibility

6.11.3.1—General

Except as specified herein, the provisions of Article 6.10.3 shall apply.

The individual box section geometry shall be maintained throughout all stages of construction. The need for temporary or permanent intermediate internal diaphragms or cross-frames, external diaphragms or cross-frames, top lateral bracing, or other means shall be investigated to ensure that deformations of the box section are controlled.

C6.11.3.1

The Engineer should consider possible eccentric loads that may occur during construction. These may include uneven placement of concrete and equipment. Temporary cross-frames or diaphragms that are not part of the original design should be removed because the structural behavior of the box section, including load distribution, may be significantly affected if these members are left in place.

Additional information on the construction of composite box sections may be found in Coletti et al. (2005) and United States Steel (1978).

For painted box sections, the Engineer should consider making an allowance for the weight of the paint. For typical structures, three percent of the steel weight is a reasonable allowance.

6.11.3.2—Flexure

For critical stages of construction, the provisions of Articles 6.10.3.2.1 through 6.10.3.2.3 shall be applied only to the top flanges of tub sections. For tub girders with a full-length top lateral bracing system, the unbraced length, L_b , for computing top flange lateral bending moments shall be taken as the distance between panel points. For tub girders with a partial-length top lateral bracing system, L_b for computing top-flange lateral bending moments shall be taken as the distance between the transition points from the laterally braced to the unbraced sections.

For tub girders with no top lateral bracing system, or with top lateral bracing systems that do not extend between 20 to 25 percent of the span length from each girder end support, an elastic buckling analysis using a three-dimensional shell-element model that captures the significant aspects of the nonprismatic geometry shall be conducted to investigate the global LTB stability of each span of an individual noncomposite tub girder for the assumed deck placement sequence.

For critical stages of construction, noncomposite box flanges in compression shall satisfy Eq. 6.11.3.2-1 in the following cases:

- The flange is longitudinally unstiffened and is not classified as compact as defined in Article 6.11.8.2.2a; or
- The flange is longitudinally stiffened and contains slender longitudinally stiffened plate panels as defined in Article E6.1.2.

$$f_{bu} \leq \frac{0.9\phi_f Ek}{\lambda_f^2} \leq \phi_f F_{yc} \quad (6.11.3.2-1)$$

In addition, for critical stages of construction, if the section under consideration has a slender web violating Eq. 6.10.6.2.3-1, Eq. 6.11.3.2-2 shall also be satisfied:

$$f_{bu} \leq \phi_f F_{crw} \quad (6.11.3.2-2)$$

where:

- λ_f = slenderness, b_f/t_f or w/t_f , of the flange plate element or longitudinally stiffened plate panel under consideration, as applicable
- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- b_f = total inside width between the plate elements providing lateral restraint to the longitudinal edges of the flange plate element under consideration (in.)
- f_{bu} = factored longitudinal stress in the compression flange of the gross cross-section calculated without consideration of longitudinal warping (ksi). The box-flange area of the gross cross-

C6.11.3.2

Although the equations of Articles 6.10.3.2.1 through 6.10.3.2.3 apply to flanges of I-sections, they may also safely be applied to a single top flange of a tub section. The provisions of Article 6.10.1.6 also apply when these equations are used. LTB between panel points need not be checked for top flanges of tub girders with a full-length or partial-length top lateral bracing system, and also need not be checked between the transition points from the laterally braced to the unbraced sections when a partial-length top lateral bracing system is used. For tub girders with no top lateral bracing system, or with top lateral bracing systems that do not extend between 20 to 25 percent of the span length from each girder end support, global LTB of each span of an individual noncomposite tub girder must be conducted as specified herein to investigate the global LTB stability of each span of the girder during the deck placement. Global LTB need not be checked for tub girders with a full-length or partial-length top lateral bracing system satisfying the recommendations provided herein.

For straight girders, lateral bending in discretely braced top flanges of tub sections, before the concrete deck has hardened or is made composite, is caused by wind and by torsion from various origins. The equations of Articles 6.10.3.2.1 and 6.10.3.2.2 allow the Engineer to directly consider the effects of the flange lateral bending, if deemed significant. When the flange lateral bending effects are judged to be insignificant or incidental, the lateral bending term, f_{li} , is simply set equal to zero in these equations. The format of the equations then reduces simply to the more conventional format for checking the flanges for the limit states of yielding, LTB or local buckling, as applicable, in the absence of flange lateral bending. For horizontally curved girders, flange lateral bending effects due to curvature must always be considered during construction. For loads applied during construction once the top flanges are continuously braced, the provisions of Article 6.10.3.2.3 apply. A distinction is made between discretely and continuously braced flanges in Article 6.10.3.2 because for a continuously braced flange, lateral flange bending need not be considered. Article C6.10.1.6 states the conditions for which top flanges may be considered continuously braced. St. Venant torsional shears are also typically neglected in continuously braced top flanges of tub sections. In checking the requirements of Articles 6.10.3.2.1 through 6.10.3.2.3 for a single top flange of a tub, it is recommended that the checks be made for half of the tub section.

One potential source of flange lateral bending due to torsion is the effect of eccentric concrete deck overhang loads acting on cantilever-forming brackets placed along exterior tub sections. In lieu of a more refined analysis, the maximum flange lateral bending moments in the outermost top flange of a tub due to these eccentric loadings may be estimated using either Eq. C6.10.3.4.1-1 or

section shall be reduced, if applicable, to account for shear lag as specified in Article 6.11.1.1 in the calculation of the stress.

F_{crw} = nominal bend-buckling resistance for webs specified in Article 6.10.1.9 (ksi)

k = plate-buckling coefficient for uniform normal stress = 4.0

t_f = thickness of the flange plate element or longitudinally stiffened flange plate panel under consideration (in.)

w = width of the box-flange plate between the centerlines of the individual longitudinal stiffeners or between the centerline of the longitudinal stiffener and the inside of the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration, as applicable (in.)

For critical stages of construction, noncomposite box flanges in tension and continuously braced box flanges in tension or compression shall satisfy the following requirement:

$$f_{bu} \leq \phi_f R_h F_{yf} \Delta \quad (6.11.3.2-3)$$

in which:

- If $\frac{f_v}{\phi_T F_{cv}} \leq 0.2$, then:

$$\Delta = 1.0 \quad (6.11.3.2-4)$$

- Otherwise:

$$\Delta = 1 - \left(\frac{f_v}{\phi_T F_{cv}} \right)^2 > 0 \quad (6.11.3.2-5)$$

f_v = factored St. Venant torsional shear stress in the flange at the section under consideration (ksi)

$$= \frac{T}{2A_o t_f} \quad (6.11.3.2-6)$$

where:

ϕ_T = resistance factor for torsion, specified in Article 6.5.4.2

A_o = cross-sectional area of the box-section member enclosed by the mid-thickness of the walls (in.²)

f_{bu} = factored longitudinal stress in the flange of the gross cross-section calculated without consideration of longitudinal warping (ksi). The box-flange area of the gross cross-section shall be reduced, if applicable, to account for shear

C6.10.3.4.1-2, depending on how the lateral load is assumed applied to the flange.

In box sections with inclined webs, the change in the horizontal component of the web dead load shear plus the change in the St. Venant torsional dead load shear per unit length along the member acts as a uniformly distributed transverse load on the girder flanges. Additional intermediate internal cross-frames, diaphragms or struts may be required to reduce the lateral bending in discretely braced top flanges of tub sections resulting from this transverse load. This may be particularly true for cases where the inclination of the web plates to a plane normal to the bottom flange is permitted to exceed 1 to 4, and/or

- lag as specified in Article 6.11.1.1 in the calculation of the stress.
- F_{cv} = nominal shear buckling resistance of the flange under shear alone calculated as specified in Article 6.11.8.2.2b (ksi). For a longitudinally stiffened flange, w shall be substituted for b_{fi} in the calculation of the flange slenderness ratio, λ_f .
- R_h = hybrid factor, determined as specified in Article 6.10.1.10.1
- t_f = thickness of the flange plate element or longitudinally stiffened flange plate panel under consideration (in.)
- T = factored torque (kip-in.)

For loads applied to a composite box flange of a closed-box section before the concrete has hardened or is made composite, the flange shall be designed as a noncomposite box flange. The maximum vertical deflection of the noncomposite box flange due to the unfactored permanent loads, including the self-weight of the flange plus the unfactored construction loads, shall not exceed $1/360$ times the transverse span between the webs. The through-thickness bending stress in the noncomposite box flange due to the factored permanent loads and factored construction loads shall not exceed 20.0 ksi. The weight of wet concrete and other temporary or permanent loads placed on a noncomposite box flange may be considered by assuming the box flange acts as a simple beam spanning between the webs. Stiffening of the flange may be used where required to control flange deflection and stresses due to loads applied before the concrete deck has hardened or is made composite.

where the unbraced length of the top flanges exceeds 30 ft. Otherwise, this transverse load can typically be ignored. The maximum lateral flange bending moments due to this transverse load can be estimated using Eq. C6.10.3.4.1-1 in lieu of a more refined analysis, where F_t is taken as the magnitude of the factored uniformly distributed transverse load. The entire transverse load should be assumed applied to the top flanges (Fan and Helwig, 1999). The cross-frame or strut can be assumed to carry the entire transverse load within the panel under consideration.

Another potential source of flange lateral bending is due to the forces that develop in Warren-type single-diagonal top lateral bracing systems due to flexure of the tub section. Refer to Article C6.7.5.3 for further discussion regarding this topic.

In cases where a partial-length top lateral bracing system is employed within a tub section, as discussed further in Article C6.7.5.3, refer to Section 6.1.1 of Armijos-Moya et al. (2019) for a recommended procedure to evaluate top-flange lateral bending. The unbraced length, L_b , for computing the top-flange lateral bending moments when a partial-length lateral bracing system is employed is to be taken as the distance between the transition points from the laterally braced to the unbraced sections, which is the controlling unbraced length; internal cross-frames or diaphragms or struts in-between the transition points are not to be considered as brace points. Also, the minimum width of the top flanges within each individual unspliced field section should satisfy the guideline given by Eq. C6.10.2.2-1, in conjunction with the flange proportion limits specified in Article 6.11.2.2. In this case, L_{fs} in Eq. C6.10.2.2-1 should be taken as the length of the individual unspliced field section that is not laterally braced. For cases where a full-length top lateral bracing system is employed, Eq. C6.10.2.2-1 need not be considered for top flanges of tub sections.

Since post-buckling resistance is assumed at the strength limit state in computing the nominal flexural resistance of noncomposite box flanges subject to compression in which the box flange is longitudinally unstiffened and not classified as compact, or the box flange is longitudinally stiffened and contains slender longitudinally stiffened plate panels, the flange in such cases must also satisfy Eq. 6.11.3.2-1 to ensure that plate local buckling due to flexural stresses does not occur theoretically during construction. Flange lateral bending and LTB are not a consideration for box flanges in composite box-section members. Refer to Figure CE6.1.3-1 for further information on the definition of the variable, w , for longitudinally stiffened box flanges.

Eq. 6.11.3.2-2 ensures that theoretical web bend-buckling will not occur during construction at sections where noncomposite box flanges are subject to compression. Eq. 6.10.3.2.1-3 serves a similar function at sections where top flanges of tub sections are subject to compression. For box sections with inclined webs,

D_c should be taken as depth of the web in compression measured along the slope in determining the web bend-buckling resistance, F_{crw} , in either case. Because the flange stress is limited to the web bend-buckling stress, the R_b factor is always to be taken equal to 1.0 in computing the nominal flexural resistance of the compression flange for constructibility. Options to consider should the flange not satisfy Eq. 6.11.3.2-2 or Eq. 6.10.3.2.1-3, as applicable, for the construction condition are discussed in Article C6.10.3.2.1. For sections with compact or noncompact webs, web bend-buckling is not a consideration, and therefore, need not be checked for these sections.

For a composite box section subjected to positive bending, the box flange at the bottom of the girder is a noncomposite box flange in tension. For a compact composite box section as defined in Article 6.11.6.2.2, this flange experiences significant yielding at the strength limit state. Eq. 6.11.3.2-3 disallows yielding of this flange during construction. For a closed-box section subjected to negative bending during construction, the box flange at the top of the girder is a noncomposite box flange in tension. Eq. 6.11.3.2-3 also disallows yielding of this flange during construction. For top flanges of composite box-section members that are considered to be continuously braced during construction, Eq. 6.11.3.2-3 disallows yielding of these flanges during construction. For noncomposite box flanges in tension, and for continuously braced box flanges in tension or compression, the influence of torsional shear on the nominal flexural resistance of the flange in cases where $f_v/\phi_T F_{cv} > 0.2$ is handled through the use of the parameter Δ given by Eq. 6.11.3.2-5. Flexural shear stresses in flanges need not be considered in Eq. 6.11.3.2-5. The flange shear stresses due to flexure, which are tangent to the wall of the flange plate, are maximum at the connection to the webs, zero at a location within the middle of the plate, and the net shear force in the flanges is zero. Further discussion on Eq. 6.11.3.2-5 is provided in Article C6.9.2.2.2.

Longitudinal warping stresses due to cross-section distortion typically need not be considered in checking Eqs. 6.11.3.2-1 and 6.11.3.2-3, but are required to be considered when checking slip of the connections in bolted flange splices for the construction condition as specified in Article 6.13.6.1.3b.

In closed-box sections, noncomposite box flanges on top of the box receive the weight of wet concrete and other loads during construction before the deck hardens or is made composite. Transverse and/or longitudinal stiffening of the box flange may be required to control box-flange deflection and stresses.

6.11.3.3—Shear

When checking the shear requirement specified in Article 6.10.3.3, the provisions of Article 6.11.9 shall also apply, as applicable.

6.11.4—Service Limit State

Except as specified herein, the provisions of Article 6.10.4 shall apply.

The f_c term in Eq. 6.10.4.2.2-2 shall be taken equal to zero. Eq. 6.10.4.2.2-3 shall not apply. Except for sections in positive flexure in which the web satisfies the requirement of Article 6.11.2.1.2, all sections shall satisfy Eq. 6.10.4.2.2-4.

For sections in negative flexure, box flanges in compression shall satisfy Eq. 6.11.4-1 at the service limit state in the following cases:

- The flange is longitudinally unstiffened and is not classified as compact as defined in Article 6.11.8.2.2a; or
- The flange is longitudinally stiffened and contains slender longitudinally stiffened plate panels as defined in Article E6.1.2.

$$f_c \leq \frac{0.9Ek}{\lambda_f^2} \leq F_{yc} \quad (6.11.4-1)$$

where:

- λ_f = slenderness, b_{β}/t_f or w/t_f of the flange plate element or longitudinally stiffened plate panel under consideration, as applicable
- b_{β} = total inside width between the plate elements providing lateral restraint to the longitudinal edges of the flange plate element under consideration (in.)
- f_c = total factored longitudinal stress in the compression flange due to the Service II loads acting on the gross cross-section under consideration calculated without consideration of longitudinal warping (ksi). The box-flange area of the gross cross-section shall be reduced, if applicable, to account for shear lag as specified in Article 6.11.1.1 in the calculation of the stress.
- k = plate-buckling coefficient for uniform normal stress = 4.0
- t_f = thickness of the flange plate element or longitudinally stiffened flange plate panel under consideration (in.)
- w = width of the plate between the centerlines of the individual longitudinal stiffeners or between the centerline of the longitudinal stiffener and the inside of the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration, as applicable (in.)

Redistribution of the negative moment due to the Service II loads at interior-pier sections in continuous-

C6.11.4

Article 6.10.4.1 refers to the provisions of Article 2.5.2.6, which contain optional live-load deflection criteria and criteria for span-to-depth ratios. In the absence of depth restrictions, the span-to-depth ratios listed for I-sections can be used to establish a reasonable minimum web depth for the design. However, because of the inherent torsional stiffness of a box section, the optimum depth for a box section will typically be slightly less than the optimum depth for an I-section of the same span. Because the size of box flanges can typically be varied less over the bridge length, establishing a sound optimum depth for box sections is especially important. Boxes that are overly shallow may be subject to larger torsional shears.

Under the load combinations specified in Table 3.4.1-1, Eqs. 6.10.4.2.2-1 and 6.10.4.2.2-2 need only be checked for compact sections in positive flexure. For sections in negative flexure and noncompact sections in positive flexure, these equations do not control and need not be checked. However, Eq. 6.10.4.2.2-4 must still be checked for these sections where applicable.

Flange lateral bending is not a consideration for box flanges, and therefore, need not be considered when checking Eq. 6.10.4.2.2-2. Flange lateral bending is not considered in Eq. 6.10.4.2.2-1 because the top flanges are continuously braced at the service limit state. Longitudinal warping stresses due to cross-section distortion need not be considered in checking the equations of Article 6.10.4.2.2, but are required to be considered when checking slip of the connections in bolted flange splices at the service limit state as specified in Article 6.13.6.1.3b. St. Venant torsional shear stresses are also not considered in checking the equations of Article 6.10.4.2.2 for box flanges. The effects of longitudinal warping stresses and torsional shear on the overall permanent deflections at the service limit state are considered to be relatively insignificant.

For box sections with inclined webs, D_c should be taken as the depth of the web in compression measured along the slope in determining the web bend-buckling resistance, F_{crwb} , for checking Eq. 6.10.4.2.2-4, where applicable.

The applicability of the optional provisions of Appendix B6 to box sections has not been demonstrated. Therefore, these provisions may not be used in the design of box sections.

Since post-buckling resistance is assumed at the strength limit state in computing the nominal flexural resistance of noncomposite box flanges subject to compression in which the box flange is longitudinally unstiffened and is not classified as compact, or the box flange is longitudinally stiffened and contains slender longitudinally stiffened plate panels, the flange in such cases must also satisfy Eq. 6.11.4-1 to ensure that plate local buckling due to flexural stresses does not occur theoretically at the service limit state. Refer to

span flexural members using the procedures specified in Appendix B6 shall not apply.

6.11.5—Fatigue and Fracture Limit State

Except as specified herein, the provisions of Article 6.10.5 shall apply.

In the calculation of dead load and live load stresses and live load stress ranges for fatigue design, the box-flange area of the gross cross-section shall be reduced, if applicable, to account for shear lag as specified in Article 6.11.1.1.

For fatigue in shear connectors, the provisions of Article 6.11.10 shall also apply, as applicable. The provisions for fatigue in shear connectors specified in Article 6.10.10.3 shall not apply.

When checking the shear requirement specified in Article 6.10.5.3, the provisions of Article 6.11.9 shall also apply, as applicable.

Longitudinal warping stresses and transverse bending stresses due to cross-section distortion shall be considered for:

- Single box sections in straight or horizontally curved bridges,
- Multiple box sections in straight bridges not satisfying the requirements of Article 6.11.2.3,
- Multiple box sections in horizontally curved bridges, or
- Any single or multiple box section with a box flange that is not fully effective according to the provisions of Article 6.11.1.1.

The stress range due to longitudinal warping shall be considered in checking the fatigue resistance of the base metal at all details on the box section according to the provisions specified in Article 6.6.1. The transverse bending stress range shall be considered separately in evaluating the fatigue resistance of the base metal adjacent to flange-to-web fillet welds and adjacent to the termination of fillet welds connecting transverse elements to webs and box flanges. The need for a bottom transverse member within the internal cross-frames to resist the transverse bending stress range in the bottom box flange at the termination of fillet welds connecting cross-frame connection plates to the flange shall be considered. Transverse cross-frame members next to box flanges shall be attached to the box flange unless flange longitudinal stiffeners are used, in which case the transverse members shall be attached to the longitudinal stiffeners by bolting. The moment of inertia of these transverse cross-frame members shall not be less than the moment of inertia of the largest connection plate for the internal cross-frame under consideration taken about the edge in contact with the web.

Figure CE6.1.3-1 for further information on the definition of the variable, w , for longitudinally stiffened box flanges.

C6.11.5

When a box section is subjected to a torsional load, its cross-section distorts and is restored at diaphragms or cross-frames. This distortion gives rise to secondary bending stresses. A torsional loading in the opposite direction produces a reversal of these distortional secondary bending stresses. In certain cases, as defined herein, these distortional stresses are to be considered when checking fatigue. Situations for which these stresses are of particular concern and for which these stresses may potentially be ignored are discussed in Article C6.11.1.1.

Where force effects in the cross-frames or diaphragms are computed from a refined analysis, stress ranges for checking load-induced fatigue and torque ranges for checking fatigue due to cross-section distortion in cross-frame and diaphragm members should be determined as recommended in Article C6.6.1.2.2. Transverse bending and longitudinal warping stress ranges due to cross-section distortion can be determined using the BEF analogy, as discussed in Article C6.11.1.1. Longitudinal warping stresses are considered additive to the longitudinal major-axis bending stresses

The most critical case for transverse bending is likely to be the base metal at the termination of fillet welds connecting transverse elements to webs and box flanges. A stress concentration occurs at the termination of these welds as a result of the transverse bending. The fatigue resistance of this detail when subject to transverse bending is not currently quantified, but is anticipated to be perhaps as low as Category E.

Should this situation be found critical in the web at transverse web stiffeners not serving as connection plates, the transverse bending stress range may be reduced by welding the stiffeners to the flanges. Attaching transverse stiffeners to the flanges reduces the sharp through-thickness bending stresses within the unstiffened portions of the web at the termination of the stiffener-to-web welds, which is usually the most critical region for this check. Cross-frame connection plates already are required to be attached to the flanges according to the provisions of Article 6.6.1.3.1 for this reason.

Should it become necessary to reduce the transverse bending stress range in the box flange adjacent to the cross-frame connection plate welds to the flange, the provision of transverse cross-frame members across the bottom of the

box or tub as part of the internal cross-bracing significantly reduces the transverse bending stress range at the welds and ensures that the cross-section shape is retained. Closer spacing of cross-frames also leads to lower transverse bending stresses. Where bottom transverse cross-frame members are provided, they are to be attached to the box flange or to the flange longitudinal stiffeners, as applicable. For closed-box sections, the top transverse cross-frame members should be similarly attached. Where transverse bracing members are welded directly to the box flange, the stress range due to transverse bending should also be considered in checking the fatigue resistance of the base metal adjacent to the termination of these welds. Where transverse bracing members are connected to flange longitudinal stiffeners, the box flange may be considered stiffened when computing the transverse bending stresses. In such cases, the transverse connection plates must still be attached to both flanges as specified in Article 6.6.1.3.1.

Load-induced fatigue is usually not critical for top lateral bracing in tub sections since the concrete deck is much stiffer and resists more of the load than does the bracing. Since the deck resists the majority of the torsional shear in these cases, it is advisable to check the reinforcement in the deck for the additional horizontal shear. Severely skewed supports may cause critical horizontal deck shear.

It is advisable to connect the lateral bracing to the top flanges to eliminate a load path through the web. Although removable deck forms are problematic in tub girders, they are sometimes required by the Owner. In such cases, it may be necessary to lower the lateral bracing by attaching it to the box webs. In these cases, connections to the webs must be made according to the requirements of Article 6.6.1.3.2 to prevent potential problems resulting from fatigue. An adequate load path, with fatigue considered, must be provided between the bracing-to-web connections and the top flanges. Connections of the lateral bracing to the web can be avoided by using metal stay-in-place deck forms.

Fatigue of the base metal at the net section of access holes or manholes should be considered. The fatigue resistance at the net section of large access holes satisfying specified geometric conditions and made to the requirements of the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code* is provided in Condition 1.6 of Table 6.6.1.2.3-1. The classification of large access holes satisfying the specified conditions as fatigue detail Category C assumes a stress concentration, or ratio of the elastic tensile stress adjacent to the hole to the average stress on the net area, of less than 2.4.

6.11.6—Strength Limit State**6.11.6.1—General**

For the purposes of this Article, the applicable Strength load combinations specified in Table 3.4.1-1 shall apply.

6.11.6.2—Flexure*6.11.6.2.1—General*

If there are holes in the tension flange at the section under consideration, the tension flange shall satisfy the requirement specified in Article 6.10.1.8.

6.11.6.2.2—Sections in Positive Flexure

Sections in horizontally curved steel-girder bridges shall be considered as noncompact sections and shall satisfy the requirements of Article 6.11.7.2.

Sections in straight bridges that satisfy the following requirements shall qualify as compact sections:

- The specified minimum yield strengths of the flanges and web do not exceed 70.0 ksi,
- The web satisfies the requirement of Article 6.11.2.1.2,
- The section is part of a bridge that satisfies the requirements of Article 6.11.2.3,
- The box flange is fully effective as specified in Article 6.11.1.1,

and:

- The section satisfies the web slenderness limit:

$$\frac{2D_{cp}}{t_w} \leq 3.76 \sqrt{\frac{E}{F_{yc}}} \quad (6.11.6.2.2-1)$$

C6.11.6.1

At the strength limit state, Article 6.11.6 directs the Engineer to the appropriate Articles for the design of box sections in regions of positive or negative flexure.

C6.11.6.2.1

Where an access hole is provided in the tension flange, the hole should be deducted in determining the gross section for checking the requirement of Article 6.10.1.8, as specified in Article 6.8.1.

A continuously braced flange in compression is assumed not to be subject to local or LTB, as applicable. The rationale for excluding these limit state checks is discussed in Article C6.10.3.2.3.

These provisions assume low or zero levels of axial force in the member and uniaxial flexure. For members that are also subject to a factored concentrically applied axial force, P_u , in excess of 5 percent of the factored axial resistance of the member, P_r or P_{ry} as applicable, at the strength limit state, and/or if the member is subject to biaxial bending, the member should instead be checked according to the provisions of Article 6.8.2.3 or 6.9.2.2, as applicable. The level of 5 percent is based conservatively on the linear interaction equations given in these Articles, which apply in the majority of cases. Below this level, it is reasonable to ignore the effect of the axial force in the design of the member.

C6.11.6.2.2

The nominal flexural resistance of sections in positive flexure within straight bridges satisfying the requirements of Article 6.11.2.3 and that also satisfy specific steel grade, web slenderness, effective flange width and ductility requirements is permitted to exceed the moment at first yield according to the provisions of Article 6.10.7. The nominal flexural resistance of these sections, termed compact sections, is therefore more appropriately expressed in terms of moment. For sections in positive flexure in straight bridges not satisfying one or more of these requirements, or for composite sections in positive flexure in horizontally curved bridges, termed noncompact sections, the nominal flexural resistance is not permitted to exceed the moment at first yield. The nominal flexural resistance in these cases is therefore more appropriately expressed in terms of the elastically computed flange stress.

For reasons discussed in Article C6.10.6.2.2, composite sections in positive flexure in straight bridges with flange yield strengths greater than 70.0 ksi or with webs that do not satisfy Article 6.11.2.1.2 or Eq. 6.11.6.2.2-1 are to be designed at the strength limit state as noncompact sections as specified in

where:

D_{cp} = depth of the web in compression at the plastic moment determined as specified in Article D6.3.2 (in.)

Compact sections shall satisfy the requirements of Article 6.11.7.1. Otherwise, the section shall be considered noncompact and shall satisfy the requirements of Article 6.11.7.2.

Compact and noncompact sections shall satisfy the ductility requirement specified in Article 6.10.7.3.

Article 6.11.7.2. Furthermore, if the section is not part of a straight bridge that satisfies the restrictions specified in Article 6.11.2.3, or is part of a horizontally curved bridge, or if the box flange is not fully effective as defined in Article 6.11.1.1, the section must be designed as a noncompact section. The ability of such sections to develop a nominal flexural resistance greater than the moment at first yield in the presence of potentially significant St. Venant torsional shear and cross-sectional distortion stresses has not been demonstrated.

Compact sections in positive flexure must satisfy the provisions of Article 6.10.7.3 to ensure a ductile mode of failure. Noncompact sections must also satisfy the ductility requirement specified in Article 6.10.7.3 to ensure a ductile failure. Satisfaction of this requirement ensures an adequate margin of safety against premature crushing of the concrete deck for sections utilizing up to 100-ksi steels and/or for sections utilized in shored construction. This requirement is also a key limit in allowing web bend-buckling to be disregarded in the design of composite sections in positive flexure when the web also satisfies Article 6.11.2.1.2, as discussed in Article C6.10.1.9.1.

6.11.6.2.3—Sections in Negative Flexure

The provisions of Article 6.11.8 shall apply. The provisions of Appendix A6 shall not apply. Redistribution of the negative moment due to the factored loads at interior-pier sections in continuous-span flexural members using the procedures specified in Appendix B6 shall not apply.

C6.11.6.2.3

For sections in negative flexure, the provisions of Article 6.11.8 limit the nominal flexural resistance to be less than or equal to the moment at first yield for all types of composite box-girder bridges. As a result, all sections in negative flexure are conservatively treated as slender-web sections at the strength limit state regardless of their web slenderness, and the nominal flexural resistance for these sections is conveniently expressed in terms of the elastically computed flange stress on the gross cross-section. The box-flange areas of the gross cross-section are to be reduced, if applicable, to account for shear lag as specified in Article 6.11.1.1 in the calculation of the stress.

The applicability of the optional provisions of Appendices A6 and B6 to box sections has not been demonstrated. Therefore, these provisions may not be used in the design of box sections.

6.11.6.3—Shear

The provisions of Article 6.11.9 shall apply.

6.11.6.4—Shear Connectors

The provisions of Article 6.10.10.4 shall apply. The provisions of Article 6.11.10 shall also apply, as applicable.

6.11.7—Flexural Resistance—Sections in Positive Flexure

6.11.7.1—Compact Sections

6.11.7.1.1—General

At the strength limit state, the section shall satisfy:

$$M_u \leq \phi_f M_n \quad (6.11.7.1.1-1)$$

where:

- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- M_n = nominal flexural resistance of the section, determined as specified in Article 6.10.7.1.2 (kip-in.)
- M_u = total factored bending moment about the major axis of the gross cross-section at the section under consideration (kip-in.)

6.11.7.1.2—Nominal Flexural Resistance

The nominal flexural resistance of the section shall be taken as specified in Article 6.10.7.1.2, except that for continuous spans, the nominal flexural resistance shall always be subject to the limitation of Eq. 6.10.7.1.2-3.

C6.11.7.1.1

For composite sections in positive flexure, lateral bending does not need to be considered in the compression flanges of tub sections at the strength limit state because the flanges are continuously supported by the concrete deck. Flange lateral bending is also not a consideration for box flanges.

C6.11.7.1.2

The equations of Article 6.10.7.1.2 are discussed in detail in Article C6.10.7.1.2.

For box sections, Eq. 6.10.7.1.2-3 is to always be used for determining the limiting nominal flexural resistance of compact sections in positive flexure in straight continuous spans. The provisions of Appendix B6, which ensure that interior-pier sections will have sufficient ductility and robustness such that the redistribution of moments caused by partial yielding within the positive flexural regions is inconsequential, are not presently applicable to box sections.

6.11.7.2—Noncompact Sections

6.11.7.2.1—General

At the strength limit state, compression flanges shall satisfy:

$$f_{bu} \leq \phi_f F_{nc} \quad (6.11.7.2.1-1)$$

where:

- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- f_{bu} = total factored longitudinal stress in the compression flange of the gross cross-section calculated without consideration of flange lateral bending or longitudinal warping, as applicable (ksi). The box-flange area of the gross cross-section shall be reduced, if applicable, to account for shear lag as specified in Article 6.11.1.1 in the calculation of the stress.

C6.11.7.2.1

For noncompact sections, the compression flange must satisfy Eq. 6.11.7.2.1-1 and the tension flange must satisfy Eq. 6.11.7.2.1-2 at the strength limit state. For composite sections in positive flexure, lateral bending does not need to be considered in the compression flanges at the strength limit state because the flanges are continuously supported by the concrete deck. Lateral bending is also not a consideration for the tension flange, which is always a box flange in this case.

For noncompact sections, the maximum total factored longitudinal stress in the concrete deck is limited to $0.6f'_c$ to ensure linear behavior of the concrete, which is assumed in the calculation of the steel flange stresses. This condition is unlikely to govern except in cases involving: (1) shored construction, or unshored construction where the noncomposite steel dead load stresses are low, combined with (2) geometries causing the neutral axis of the short-term and long-term

F_{nc} = nominal flexural resistance of the compression flange determined as specified in Article 6.11.7.2.2 (ksi) composite section to be significantly below the bottom of the concrete deck.

The tension flange shall satisfy:

$$f_{bu} \leq \phi_f F_{nt} \quad (6.11.7.2.1-2)$$

where:

F_{nt} = nominal flexural resistance of the tension flange determined as specified in Article 6.11.7.2.2 (ksi)

f_{bu} = total factored longitudinal stress in the tension flange of the gross cross-section calculated without consideration of flange lateral bending or longitudinal warping, as applicable (ksi). The box-flange area of the gross cross-section shall be reduced, if applicable, to account for shear lag as specified in Article 6.11.1.1 in the calculation of the stress.

The maximum total factored longitudinal compressive stress in the concrete deck at the strength limit state, determined as specified in Article 6.10.1.1.1d, shall not exceed $0.6 f'_c$.

6.11.7.2.2—Nominal Flexural Resistance

The nominal flexural resistance of the compression flanges of tub sections shall be taken as:

$$F_{nc} = R_b R_h F_{yc} \quad (6.11.7.2.2-1)$$

where:

R_b = web load-shedding factor, determined as specified in Article 6.10.1.10.2

R_h = hybrid factor, determined as specified in Article 6.10.1.10.1

The nominal flexural resistance of the composite compression flange of closed-box sections shall be taken as:

$$F_{nc} = R_b R_h F_{yc} \Delta \quad (6.11.7.2.2-2)$$

in which:

- If $\frac{f_v}{\phi_f F_{cv}} \leq 0.2$, then:

$$\Delta = 1.0 \quad (6.11.7.2.2-3)$$

- Otherwise:

C6.11.7.2.2

The nominal flexural resistance of noncompact sections in positive flexure is limited to the moment at first yield. Thus, the nominal flexural resistance is expressed simply in terms of the flange stresses. For noncompact sections, the elastically computed total factored stress in each flange, determined in accordance with Articles 6.10.1.1.1a and 6.10.1.1.1b, is compared with the yield stress of the flange times the appropriate flange stress reduction factors.

For box flanges, the effect of the St. Venant torsional shear stress in the flange must also be considered where necessary. The computation of the flange torsional shear stress from Eq. 6.11.7.2.2-5 or 6.11.7.2.2-9, as applicable, due to torques applied separately to the noncomposite and composite sections is discussed in Article C6.11.1.1.

$$\Delta = 1 - \left(\frac{f_v}{\phi_T F_{cv}} \right)^2 > 0 \quad (6.11.7.2.2-4)$$

f_v = total factored St. Venant torsional shear stress in the compression flange at the section under consideration (ksi)

$$= \frac{T}{2A_o t_{fc}} \quad (6.11.7.2.2-5)$$

where:

ϕ_T = resistance factor for torsion, specified in Article 6.5.4.2

A_o = cross-sectional area of the box-section member enclosed by the mid-thickness of the walls and concrete deck as applicable (in.²)

F_{cv} = nominal shear buckling resistance of the flange subjected to shear alone, calculated as specified in Article 6.11.8.2.2b (ksi). For a longitudinally stiffened flange, w shall be substituted for b_{fi} in the calculation of the flange slenderness ratio, λ_{yf} .

t_{fc} = thickness of the compression-flange plate element or longitudinally stiffened compression-flange plate panel under consideration (in.)

T = factored torque (kip-in.)

The nominal flexural resistance of the tension flange of closed-box and tub sections shall be taken as:

$$F_{nt} = R_h F_{yt} \Delta \quad (6.11.7.2.2-6)$$

in which:

- If $\frac{f_v}{\phi_T F_{cv}} \leq 0.2$, then:

$$\Delta = 1.0 \quad (6.11.7.2.2-7)$$

- Otherwise:

$$\Delta = 1 - \left(\frac{f_v}{\phi_T F_{cv}} \right)^2 > 0 \quad (6.11.7.2.2-8)$$

f_v = total factored St. Venant torsional shear stress in the tension flange at the section under consideration (ksi)

$$= \frac{T}{2A_o t_{ft}} \quad (6.11.7.2.2-9)$$

where:

- ϕ_T = resistance factor for torsion, specified in Article 6.5.4.2
- A_o = cross-sectional area of the box-section member enclosed by the mid-thickness of the walls and concrete deck as applicable (in.²)
- F_{cv} = nominal shear buckling resistance of the flange subjected to shear alone, calculated as specified in Article 6.11.8.2.2b (ksi). For a longitudinally stiffened flange, w shall be substituted for b_{fi} in the calculation of the flange slenderness ratio, λ_f .
- t_{fi} = thickness of the tension-flange plate element or longitudinally stiffened tension-flange plate panel under consideration (in.)
- T = factored torque (kip-in.)

6.11.8—Flexural Resistance—Sections in Negative Flexure

6.11.8.1—General

6.11.8.1.1—Box Flanges in Compression

At the strength limit state, the following requirement shall be satisfied:

$$f_{bu} \leq \phi_f F_{nc} \quad (6.11.8.1.1-1)$$

where:

- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- f_{bu} = factored longitudinal stress in the compression flange of the gross cross-section calculated without consideration of longitudinal warping (ksi). The box-flange area of the gross cross-section shall be reduced, if applicable, to account for shear lag, as specified in Article 6.11.1.1 in the calculation of the stress.
- F_{nc} = nominal flexural resistance of the flange, determined as specified in Article 6.11.8.2 (ksi)

C6.11.8.1.1

Eq. 6.11.8.1.1-1 ensures that box flanges in compression have sufficient strength with respect to FLB. Flange lateral bending and LTB are not a consideration for box flanges in composite box-section members.

In general, bottom box flanges at interior-pier sections are subjected to biaxial stresses due to major-axis bending of the box section and major-axis bending of the internal diaphragm over the bearing sole plate. The flange is also subject to shear stresses due to the internal diaphragm vertical shear, and in cases where it must be considered, the St. Venant torsional shear. Bending of the internal diaphragm over the bearing sole plate can be particularly significant for boxes supported on single bearings. For cases where the shear stresses and/or bending of the internal diaphragm are deemed significant, the following equation may be used to check this combined stress state in the box flange at the strength limit state:

$$\sqrt{f_{bu}^2 - f_{bu}f_{by} + f_{by}^2 + 3(f_d + f_v)^2} \leq \phi_f R_b R_{fc} F_{yc} \left(\frac{M_{yc}}{M_{yc}} \right) \quad (C6.11.8.1.1-1)$$

where:

- f_{by} = total factored stress in the compression flange of the gross cross-section caused by major-axis bending of the internal diaphragm over the bearing sole plate (ksi)
- f_d = total factored shear stress in the compression flange of the gross cross-section caused by the internal diaphragm vertical shear (ksi)
- f_v = total factored St. Venant torsional shear stress in the gross cross-sectional area of the compression flange (ksi)
- M_{yc} = yield moment with respect to the compression flange determined as specified in Article D6.2.1

or D6.2.3, as applicable, using the gross cross-section including corner areas and flange extensions (kip-in.). The box-flange area of the gross cross-section shall not be reduced to account for shear lag in the calculation. For a section with a longitudinally stiffened box flange subject to compression, refer also to Article 6.11.8.2.3.

M_{yc} = yield moment with respect to the compression flange determined as specified in Article D6.2.1 or D6.2.3, as applicable, using the effective width of the compression flange, b_{ec} , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} and including the width of the corner areas and flange extensions (kip-in.). The box-flange area of the cross-section shall not be reduced to account for shear lag in the calculation. For a section with a longitudinally stiffened box flange subject to compression, refer also to Article 6.11.8.2.3.

R_b = web load-shedding factor determined as specified in Article 6.10.1.10.2. In applying the provisions of Article 6.10.1.10.2, a_{wc} shall be determined with $b_{fc}t_{fc}$ taken as one-half of the compression-flange area for a longitudinally unstiffened box flange with the flange classified as compact as defined in Article 6.11.8.2.2a, and as one-half of the effective compression-flange area, $b_{ec}t_{fc}/2$, for a longitudinally unstiffened box flange with the flange not classified as compact; for a section with a compact box flange, D_c shall be taken as the depth of the web in compression determined as specified in Article D6.3.1; for a section with a box flange not classified as compact, D_c shall be taken as the depth of the web in compression using the effective cross-section, D_{ce} , based on the use of the effective width of the compression flange, b_e . The total effective width of the compression flange, b_e , shall be determined by calculating the effective clear width between the webs as specified in Article 6.9.4.2.2b, with F_{cr} taken equal to F_y , and adding the widths of the corner areas and the flange extensions to this width. For a section with a longitudinally stiffened box flange subject to compression, refer to the definition of R_b given in Article 6.11.8.2.3.

R_h = hybrid factor determined as specified in Article 6.10.1.10.1. In applying the provisions of Article 6.10.1.10.1, for cross-sections in which D_n is the distance from the elastic neutral axis to the compression flange, A_{fh} shall be taken as one-half of the compression-flange area for a longitudinally unstiffened box flange with the flange classified as compact as defined in Article 6.11.8.2.2a, and as one-half of the effective compression-flange area, $b_{effc}/2$, for a longitudinally unstiffened box flange with the

flange not classified as compact, including corner areas and flange extensions; for cross-sections in which D_n is the distance from the elastic neutral axis to the tension flange, A_{fn} shall be taken as one-half of the tension-flange area, including corner areas, flange extensions, and any tension-flange longitudinal stiffeners. For a section with a longitudinally stiffened box flange subject to compression, refer to the definition of R_h given in Article 6.11.8.2.3.

Eq. C6.11.8.1.1-1 represents the general form of the Huber-von Mises-Hencky yield criterion (Ugural and Fenster, 1978). Refer to Article C6.11.8.2.2b for further discussion on the ratio of M_{yc} to M_{ye} in Eq. C6.11.8.1.1-1.

For a box supported on two bearings, f_{by} in Eq. C6.11.8.1.1-1 is typically relatively small and can often be neglected.

The box flange may be considered effective with the internal diaphragm at interior-pier sections in making this check. A flange width equal to six times its thickness may be considered effective with the internal diaphragm. The shear stress in the flange, f_d , caused by the internal diaphragm vertical shear due to the factored loads can then be estimated as:

$$f_d = \frac{VQ}{It_{fc}} \quad (\text{C6.11.8.1.1-2})$$

where:

- V = vertical shear in the internal diaphragm due to flexure plus St. Venant torsion (kip)
- Q = first moment of one-half the effective box-flange area about the neutral axis of the effective internal diaphragm section (in.³)
- I = moment of inertia of the effective internal diaphragm section (in.⁴)

Wherever an access hole is provided within the internal diaphragm, the effect of the hole should be considered in computing the section properties of the effective diaphragm section.

6.11.8.1.2—Continuously Braced Flanges in Tension

C6.11.8.1.2

At the strength limit state, the following requirement shall be satisfied:

$$f_{bu} \leq \phi_f F_{nt} \quad (6.11.8.1.2-1)$$

where:

ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2

For continuously braced top flanges of tub sections, lateral flange bending need not be considered. St. Venant torsional shears are also typically neglected. The torsional shears may not be neglected, however, in a continuously braced box flange.

F_{nt} = nominal flexural resistance based on tension-flange yielding, determined as specified in Article 6.11.8.3 (ksi)

6.11.8.2—Flexural Resistance of Noncomposite Box Flanges in Compression

6.11.8.2.1—General

The nominal flexural resistance of longitudinally unstiffened noncomposite box flanges in compression shall be determined as specified in Article 6.11.8.2.2. The nominal flexural resistance of longitudinally stiffened noncomposite box flanges in compression shall be determined as specified in Article 6.11.8.2.3.

6.11.8.2.2—Longitudinally Unstiffened Flanges

6.11.8.2.2a—Classification of Longitudinally Unstiffened Flanges

A longitudinally unstiffened flange satisfying the following:

$$\lambda_f \leq \lambda_{pf} \quad (6.11.8.2.2a-1)$$

is classified as a compact flange.

In which:

λ_f = flange slenderness

$$= \frac{b_f}{t_f} \quad (6.11.8.2.2a-2)$$

$$\lambda_{pf} = 1.09 \sqrt{\frac{E}{F_{yc}}} \quad (6.11.8.2.2a-3)$$

where:

b_f = clear width of the flange under consideration between the webs (in.)

t_f = thickness of the flange under consideration (in.)

C6.11.8.2.2a

Sections with longitudinally unstiffened box flanges having a slenderness, λ_f , that satisfies the limit in uniform axial compression, λ_{pf} , given by Eq. 6.11.8.2.2a-3 are defined herein as compact. For welded built-up box sections, λ_{pf} as specified by these provisions is comparable to the compact flange limit in AISC (2022b), and it is comparable to the Class 1 flange limit in CEN (2005), which is intended to ensure that the section can form a plastic hinge with a rotation capacity sufficient for plastic analysis, contingent on the satisfaction of other necessary plate slenderness and unbraced length requirements. This more restrictive limit is also related to the shift in Winter's classical plate effective width curve for welded built-up box sections discussed in Article C6.9.4.2.2b. Longitudinally unstiffened box flanges in compression with a slenderness larger than λ_{pf} have a compression flange effective width smaller than the gross width of the flange.

The Article 6.11.8.2.2 provisions parallel the provisions of Article 6.12.2.2.2c for noncomposite box-section members, but conservatively limit the maximum calculated resistance of the composite box section in negative bending to the yield moment by implicitly taking $R_{pc} = 1.0$ throughout. This is a practical simplification, since it would rarely be economical to make the two webs compact for a composite box section in negative bending. In addition, the Article 6.11.8.3 provisions employ the conservative approach of limiting the calculated composite box-section resistance to the first-yield strength of the tension flanges. This is a practical simplification in that there is little economy to be gained by making composite box sections in negative bending highly singly symmetric with a large box flange in compression and a neutral axis close to the box flange. Given the simplification that R_{pc} is implicitly always taken equal to 1.0 in Article 6.11.8.2.2, the conservative application of the tension flange first-yield strength

condition, and the fact that extremely long noncomposite cases, potentially with combined bending and axial force and small moment gradients, are not of concern for composite box-section members, it is sufficient and accurate to take the R_f parameter of Article 6.12.2.2.2c equal to 1.0 in all cases in Article 6.11.8.2.2.

The calculated resistances using the Article 6.11.8.2.2 provisions are a close match to the resistances predicted by the Eurocode (CEN; 2005, 2006) involving an explicit determination of the plate effective widths in both the box flange in compression as well as the compressed region of the webs. These calculated resistances also provide a more consistent calculation with the handling of Δ than previous Specifications, and the results are a close match to the resistances for box flanges from the previous Specifications that were governed by the plateau strength or the inelastic flange buckling strength. For thinner box flanges in compression that were restricted to the theoretical elastic buckling strength in the previous Specifications, the provisions of Article 6.11.8.2.2 can provide significantly larger resistances. These provisions also provide a more natural, economical, and workable transition to the use of longitudinally stiffened box flanges for relatively wide composite box sections.

6.11.8.2.2b—General Yielding and Compression FLB

The nominal flexural resistance of the compression flange on the gross cross-sectional area based on the combined influence of general yielding and local buckling, F_{nc} , shall be determined as follows:

$$F_{nc} = R_b R_h R_{fc} \Delta \frac{M_{ycc}}{M_{yc}} \quad (6.11.8.2.2b-1)$$

in which:

- If $\frac{f_v}{\phi_T F_{cv}} \leq 0.2$, then:

$$\Delta = 1.0 \quad (6.11.8.2.2b-2)$$

- Otherwise:

$$\Delta = 1 - \left(\frac{f_v}{\phi_T F_{cv}} \right)^2 > 0 \quad (6.11.8.2.2b-3)$$

f_v = total factored St. Venant torsional shear stress on the gross cross-sectional area of the compression flange (ksi)

$$= \frac{T}{2 A_o t_{fc}} \quad (6.11.8.2.2b-4)$$

C6.11.8.2.2b

For longitudinally unstiffened noncomposite box flanges, the slenderness is based on the clear flange width between webs, b_{fi} .

Eq. 6.11.8.2.2b-1 quantifies the nominal flexural resistance of noncomposite box flanges in flexural compression in composite box-section members based on the combined influence of general yielding and FLB. FLB is considered through the use of an effective cross-section, considering the post-buckling response of box flanges subject to compression that are not classified as compact as defined in Article 6.11.8.2.2a. The influence of the reduced compression-flange effective width on the flexural resistance is addressed by multiplying the resistance by the ratio of M_{ycc} to M_{yc} . The corresponding compression-flange stresses are calculated on the gross cross-section with a reduction in the gross box-section width to account for shear lag in extreme cases where the box-flange width exceeds one-fifth of the effective span as specified in Article 6.11.1.1. Box flanges subject to compression, which are supported by webs along two longitudinal edges, have substantial post-buckling resistance.

For sections with a longitudinally unstiffened compact box flange in compression, M_{ycc} is equal to M_{yc} , and therefore the ratio of these terms in Eq. 6.11.8.2.2b-1 is equal to 1.0.

The reduction in the flexural resistance under uniform bending due to the limit state of LTB is considered to be negligible for composite box-section members.

F_{cv} = nominal shear buckling resistance on the gross cross-sectional area of the flange under shear alone calculated as follows (ksi):

- If $\lambda_f \leq 1.12 \sqrt{\frac{Ek_s}{F_{yc}}}$, then:

$$F_{cv} = 0.58F_{yc} \quad (6.11.8.2.2b-5)$$

- If $1.12 \sqrt{\frac{Ek_s}{F_{yc}}} < \lambda_f \leq 1.40 \sqrt{\frac{Ek_s}{F_{yc}}}$, then:

$$F_{cv} = \frac{0.65 \sqrt{F_{yc} Ek_s}}{\lambda_f} \quad (6.11.8.2.2b-6)$$

- If $\lambda_f > 1.40 \sqrt{\frac{Ek_s}{F_{yc}}}$, then:

$$F_{cv} = \frac{0.9 Ek_s}{\lambda_f^2} \quad (6.11.8.2.2b-7)$$

λ_f = flange slenderness ratio

$$= \frac{b_{fi}}{t_{fc}} \quad (6.11.8.2.2b-8)$$

k_s = plate-buckling coefficient for shear stress
= 5.34

where:

ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2

ϕ_T = resistance factor for torsion, specified in Article 6.5.4.2

b_{fi} = clear width of the flange under consideration between the webs (in.)

A_o = cross-sectional area of the box-section member enclosed by the mid-thickness of the walls, and concrete deck as applicable (in.²)

R_b = web load-shedding factor determined as specified in Article 6.10.1.10.2. In applying the provisions of Article 6.10.1.10.2, a_{wc} shall be determined with $b_{fc}t_{fc}$ taken as one-half of the compression-flange area for a longitudinally unstiffened box flange with the flange classified as compact as defined in Article 6.11.8.2.2a, and as one-half of the effective compression-flange area, $b_{efc}/2$, for a longitudinally unstiffened box flange with the flange not classified as compact; for a section with a compact box flange, D_c shall be taken as the depth of the web in compression

The influence of torsional shear on the nominal flexural resistance of the flange in cases where $f_v/\phi_T F_{cv} > 0.2$ is handled through the use of the parameter Δ given by Eq. 6.11.8.2.2b-3. Flexural shear stresses in flanges need not be considered in Eq. 6.11.8.2.2b-3. The flange shear stresses due to flexure, which are tangent to the wall of the flange plate, are maximum at the connection to the webs, zero at a location within the middle of the plate, and the net shear force in the flanges is zero. Further discussion on Eq. 6.11.8.2.2b-3 is provided in Article C6.9.2.2.2.

The equations for the nominal shear buckling resistance on the gross cross-sectional area of the compression flange under shear alone, F_{cv} , are determined from the equations for the constant, C , given in Article 6.10.9.3.2, where C is the ratio of the shear buckling resistance to the shear yield strength of the flange taken as $F_{yc}/\sqrt{3}$.

The computation of the total factored St. Venant torsional shear stress on the gross cross-sectional area of the compression flange, f_v , from Eq. 6.11.8.2.2b-4 due to torques applied separately to the noncomposite and composite sections is discussed in Article C6.11.1.1.

The specified shear buckling coefficient, k_s , assumes simply supported boundary conditions at the edges of the flanges (Timoshenko and Gere, 1961).

The term R_b is a post-buckling strength reduction factor that accounts for the reduction in the section flexural resistance caused by the shedding of compressive stresses from a slender web and the corresponding increase in the flexural stress within the compression flange. This term is an approximation of the ratio of M_{yc}/M_{yc} due to the reduced effective web area in compression but provides a noniterative accounting for the reduced effective web area. The effective width reduction of the compression flange is accounted for explicitly, since this reduction does not require iteration in determining the effective section properties. The R_h factor accounts for the reduced contribution of the web to the nominal flexural resistance at first yield in any flange element, due to earlier yielding of the lower-strength steel in the web of a hybrid section. The R_b and R_h factors are discussed in greater detail in Articles C6.10.1.10.2 and C6.10.1.10.1, respectively.

determined as specified in Article D6.3.1; for a section with a box flange not classified as compact, D_c shall be taken as the depth of the web in compression using the effective cross-section, D_{ce} , based on the use of the effective width of the compression flange, b_e . The total effective width of the compression flange, b_e , shall be determined by calculating the effective clear width between the webs as specified in Article 6.9.4.2.2b, with F_{cr} taken equal to F_y , and adding the widths of the corner areas and the flange extensions to this width.

R_h = hybrid factor, determined as specified in Article 6.10.1.10.1. In applying the provisions of Article 6.10.1.10.1, for cross-sections in which D_n is the distance from the elastic neutral axis to the compression flange, A_{fn} shall be taken as one-half of the compression-flange area for a longitudinally unstiffened box flange with the flange classified as compact as defined in Article 6.11.8.2.2a, and as one-half of the effective compression-flange area, $b_e t_{fc}/2$, for a longitudinally unstiffened box flange with the flange not classified as compact, including corner areas and flange extensions; for cross-sections in which D_n is the distance from the elastic neutral axis to the tension flange, A_{fn} shall be taken as one-half of the tension-flange area, including corner areas, flange extensions, and any tension-flange longitudinal stiffeners.

M_{yc} = yield moment with respect to the compression flange determined as specified in Article D6.2.1 or D6.2.3, as applicable, using the gross cross-section including corner areas and flange extensions (kip-in.). The box-flange area of the gross cross-section shall not be reduced to account for shear lag in the calculation.

M_{yce} = yield moment with respect to the compression flange determined as specified in Article D6.2.1 or D6.2.3, as applicable, using the effective width of the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} and including the width of the corner areas and flange extensions (kip-in.). The box-flange area of the cross-section shall not be reduced to account for shear lag in the calculation.

t_{fc} = thickness of the compression flange (in.)

T = factored torque (kip-in.)

6.11.8.2.3—Longitudinally Stiffened Flanges

The nominal flexural resistance of a longitudinally stiffened compression flange shall be taken as equal to the nominal flexural resistance for a longitudinally unstiffened compression flange, determined as specified in Article 6.11.8.2.2b, with the following substitutions:

C6.11.8.2.3

When a noncomposite longitudinally unstiffened box flange becomes so slender that nominal flexural resistance of the flange decreases to an impractical level, longitudinal stiffeners can be added to the flange. However, given the resistances provided for thin

- For the purpose of calculating the nominal flexural resistance, F_{nc} , in Article 6.11.8.2.2b, the longitudinally stiffened compression flange shall be represented by the following effective area located at the centroid of the gross area of the flange plate and its longitudinal stiffeners in the calculation of the yield moment of the effective cross-section with respect to the compression flange, M_{yc} :

$$A_{eff} = \frac{P_{nsp}}{F_{yc}} \quad (6.11.8.2.3-1)$$

where:

P_{nsp} = nominal compressive resistance of the compression flange calculated as specified in Article E6.1.3 (kip)

F_{yc} = specified minimum yield strength of the longitudinally stiffened compression flange (ksi)

- The yield moment of the effective cross-section with respect to the compression flange, M_{yc} , in Eq. 6.11.8.2.2b-1 shall be determined as specified in Article D6.2.1 or D6.2.3, as applicable. The effective section modulus, $S_{x_{eff}}$, used in the calculation of M_{yc} shall be determined by dividing the appropriate corresponding effective moment of inertia, I_{xe} , by the distance to the extreme fiber of the actual compression flange, where I_{xe} is calculated using the effective area, A_{eff} . The corner areas and the areas of the flange extensions should be included, in addition to the compression flange effective area, in the calculation of I_{xe} . The box-flange area of the cross-section shall not be reduced to account for shear lag in the calculation.
- The yield moment with respect to the compression flange, M_{yc} , in Eq. 6.11.8.2.2b-1 shall be determined as specified in Article D6.2.1 or D6.2.3, as applicable, using the gross cross-section including corner areas and flange extensions. The area of the flange longitudinal stiffeners should also be included in the calculation of M_{yc} . The box-flange area of the gross cross-section shall not be reduced to account for shear lag in the calculation.
- The web load-shedding factor, R_b , in Eq. 6.11.8.2.2b-1 shall be determined using the applicable provisions of Article 6.10.1.10.2. In applying the provisions of Article 6.10.1.10.2, a_{wc} shall be determined with $b_{fc}t_{fc}$ taken as $A_{eff}/2$; D_c shall be taken as the depth of the web in

longitudinally unstiffened box flanges by the provisions of Article 6.11.8.2.2b, it is apparent that there is essentially no economy to be realized due to longitudinal stiffening in new construction, even for the widest of typical tub girders, unless the constructibility and service flange stress limits on the unstiffened flange specified in Articles 6.11.3.2 and 6.11.4, respectively, are violated. Even in these cases, the more economical route for typical tub girders would likely be to thicken the flange, rather than to provide longitudinal stiffening. Therefore, the provisions specified herein are anticipated to be most useful in the context of rating of existing composite box-girder bridges with flange longitudinal stiffeners.

The nominal flexural resistance of a longitudinally stiffened box flange is determined using the same equation specified for longitudinally unstiffened box flanges in Article 6.11.8.2.2b. The calculation of the effective area of the compression flange using Eq. 6.11.8.2.3-1 quantifies the flexural resistance of these types of box-section members accurately to conservatively (Lokhande and White, 2018).

It should be noted that when Eq. 6.11.8.2.2b-1 is applied for a box section containing a longitudinally stiffened box flange in compression, M_{yc} is typically smaller than M_{yc} even when the individual panels of the flange between the longitudinal stiffeners are compact. This is because the effective area of the longitudinally stiffened flange includes an accounting for the capacity of the longitudinal stiffeners acting effectively as compression struts on an elastic foundation.

In cases where flange longitudinal stiffeners are provided but are not required for strength, the longitudinal stiffeners may be neglected, and the flange may be considered as longitudinally unstiffened for purposes of calculating the member resistance. However, all requirements pertaining to the longitudinal stiffeners must be satisfied for such sections. The shear buckling coefficient, k_s , for a stiffened plate to be used in Eqs. 6.11.8.2.2b-5 through 6.11.8.2.2b-7 is given by Eq. 6.11.8.2.3-2, which comes from Culver (1972). White et al. (2019b) provide alternative equations, derived from Eurocode 3 Part 1-5, that quantify the shear buckling resistance for longitudinally stiffened box flanges having any number of longitudinal stiffeners, not necessarily equally spaced, which account for the additional lateral restraint from transverse stiffeners when the transverse stiffeners are spaced at less than or equal to three times the plate width. These equations may be employed to realize a larger shear resistance for close transverse stiffener spacing.

Flange longitudinal stiffeners are best discontinued at field splice locations, particularly when the span balance is such that the box flange on the other side of the field splice need not be stiffened. To accomplish this successfully, the flange splice plates must be split to allow the stiffener to be taken to the free edge of the flange where the flange normal stress is zero. The compressive resistance of the unstiffened box flange on

compression determined as specified in Article D6.3.1 using the effective cross-section, D_{ce} . The corner areas and the areas of the flange extensions should be included, in addition to the compression flange effective area, in the calculation of D_{ce} .

- In the calculation of the hybrid factor, R_h , in Eq. 6.11.8.2.2b-1 using the provisions of Article 6.10.1.10.1, when D_n is the distance from the elastic neutral axis to the compression flange, A_{fn} shall be taken as $A_{eff}/2$; when D_n is the distance from the elastic neutral axis to the tension flange, A_{fn} shall be taken as one-half the total tension flange area including corner areas, flange extensions, and any tension-flange longitudinal stiffeners.
- For the purpose of calculating the nominal shear buckling resistance, F_{cv} in Article 6.11.8.2.2b, the width w_{max} shall be substituted for b_{fi} .
- The plate-buckling coefficient for shear stress, k_s in Eqs. 6.11.8.2.2b-5 through 6.11.8.2.2b-7, shall be taken as:

$$k_s = \frac{5.34 + 2.84 \left(\frac{I_s}{w_{max}^3 t_{fc}^3} \right)^{\frac{1}{3}}}{(n+1)^2} \leq 5.34 \quad (6.11.8.2.3-2)$$

where:

- I_s = moment of inertia of a single flange longitudinal stiffener about an axis parallel to the flange and taken at the base of the stiffener (in.⁴)
- n = number of equally spaced flange longitudinal stiffeners
- w_{max} = larger of the width of the flange between flange longitudinal stiffeners or the distance from a web to the nearest flange longitudinal stiffener (in.)

Flange longitudinal stiffeners shall satisfy the provisions of Article E6.1.4. Transverse stiffeners, when utilized to strengthen or stiffen a longitudinally stiffened flange, shall satisfy the requirements of Article E6.1.5.

6.11.8.3—Flexural Resistance Based on Tension-Flange Yielding

The nominal flexural resistance of tub sections based on tension-flange yielding shall be taken as:

$$F_{nt} = R_h F_{yt} \quad (6.11.8.3-1)$$

where:

the other side of the splice should be checked. Otherwise, if the stiffener must be discontinued in a region subject to a net tensile stress, determined as specified in Article 6.6.1.2.1, the termination of the stiffener-to-flange weld must be checked for fatigue according to the terminus detail. Where it becomes necessary to run the stiffener beyond the field splice, splicing the stiffener across the field splice is recommended.

C6.11.8.3

For sections in which $M_{yt} > M_{yc}$, Eq. 6.11.8.3-1 or Eq. 6.11.7.2.2-6, as applicable, does not control and tension-flange yielding need not be checked, where M_{yc} and M_{yt} are the yield moments with respect to the compression and tension flange, respectively, determined as specified in Article D6.2. Although strictly it would be correct to calculate and apply a ratio of the effective and

R_h = hybrid factor, determined as specified in Article 6.10.1.10.1

The nominal flexural resistance of closed-box sections based on tension-flange yielding shall be determined from Eq. 6.11.7.2.2-6.

6.11.9—Shear Resistance

Except as specified herein, the provisions of Article 6.10.9 shall apply for determining the factored shear resistance of a single web. For the case of inclined webs, D in Article 6.10.9 shall be taken as the depth of the web plate measured along the slope.

For the case of inclined webs, each web shall be designed for a shear, V_u , due to the factored loads taken as:

$$V_u = \frac{V_u}{\cos \theta} \quad (6.11.9-1)$$

where:

- V_u = vertical shear due to the factored loads on one inclined web (kip)
- θ = the angle of inclination of the web plate to the vertical (degrees)

For all single box sections, horizontally curved sections, and multiple box sections in bridges not satisfying the requirements of Article 6.11.2.3, or with box flanges that are not fully effective according to the provisions of Article 6.11.1.1, V_u shall be taken as the sum of the flexural and St. Venant torsional shears.

In checking Eq. 6.10.9.3.2-1, b_{fc} for box flanges shall be taken as one-half of the effective width between webs calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} for longitudinally unstiffened compression flanges, and as one-half the effective area between webs determined as specified in Article 6.11.8.2.3, including the longitudinal stiffeners, divided by the thickness of the plate for longitudinally stiffened compression flanges. The width, b_{fb} , for box flanges shall be taken as one-half the gross area of the tension flange, including any longitudinal stiffeners, divided by the thickness of the plate. Shear lag effects shall be considered, as applicable, in the determination of b_{fc} and b_{fb} , as specified in Article 6.11.1.1.

Web stiffeners shall satisfy the requirements of Article 6.11.11.

6.11.10—Shear Connectors

Except as specified herein, shear connectors shall be designed according to the provisions of Article 6.10.10.

Shear connectors shall be provided in negative flexure regions.

gross yield moments to the tension flange, M_{yte}/M_{yt} , in Eq. 6.11.8.3-1, the effect of multiplying by this term tends to be small. For similar reasons, an R_b factor is not applied to the tension flange.

C6.11.9

For boxes with inclined webs, the web must be designed for the component of the vertical shear in the plane of the web.

Usually, the box webs are detailed with equal height webs. If the deck is superelevated, the box may be rotated to match the deck slope, which is generally preferred to simplify fabrication by maintaining symmetry of the girder sections. The result is that the inclination of one web is increased over what it would have been if the box were not rotated. The computed shear in that web due to vertically applied loads should be adjusted accordingly.

For the box sections specifically cited in this Article, including sections in horizontally curved bridges, St. Venant torsional shear must be considered in the design of the webs. The total shear in one web is greater than in the other web at the same section since the torsional shear is of opposite sign in the two webs. As a matter of practicality, both webs can be designed for the critical shear.

Although shear and longitudinal stresses in the webs due to warping are not zero, these effects are typically quite small and can be ignored in the design of the webs.

For multiple box sections in straight bridges satisfying the requirements of Article 6.11.2.3 for which a live load distribution factor for moment is employed, one-half the distribution factor for moment should be used in the calculation of the live load vertical shear in each web.

C6.11.10

Shear connectors must be present in regions of negative flexure to resist the torsional shear that exists along the entire span in all types of composite box sections. Also, the prototype and model bridges that were studied in the original development of the live-load

For all single box sections, horizontally curved sections, and multiple box sections in bridges not satisfying the requirements of Article 6.11.2.3, or with box flanges that are not fully effective according to the provisions of Article 6.11.1.1, shear connectors shall be designed for the sum of the flexural and St. Venant torsional shears. The longitudinal fatigue shear range per unit length, V_{fat} , for one top flange of a tub girder shall be computed for the web subjected to additive flexural and torsional shears. The resulting shear connector pitch shall also be used for the other top flange. The radial fatigue shear range due to curvature, F_{fat1} , given by Eq. 6.10.10.1.2-5 may be ignored in the design of box sections in straight or horizontally curved spans or segments.

For checking the resulting number of shear connectors to satisfy the strength limit state, the cross-sectional area of the steel box section under consideration and the effective area of the concrete deck associated with that box shall be used in determining P by Eqs. 6.10.10.4.2-2, 6.10.10.4.2-3, 6.10.10.4.2-7, and 6.10.10.4.2-8.

Shear connectors on composite box flanges shall be uniformly distributed across the width of the flange. The maximum transverse spacing, s_t , between shear connectors on composite box flanges shall satisfy the following requirement:

$$\frac{s_t}{t_f} \sqrt{\frac{F_{yf}}{kE}} \leq \lambda_{pf} \quad (6.11.10-1)$$

where:

- k = plate-buckling coefficient for uniform normal stress, determined as specified in Article 6.11.3.2
- λ_{pf} = limiting slenderness ratio for the box flange, determined from Eq. 6.11.8.2.2a-3

For composite box flanges at the fatigue limit state, V_{sf} in Eq. 6.10.10.1.2-1 shall be determined as the vector sum of the longitudinal fatigue shear range given by Eq. 6.10.10.1.2-4 and the torsional fatigue shear range in the concrete deck. The number of shear connectors required to satisfy the strength limit state shall be determined according to the provisions of Article 6.10.10.4. In addition, the vector sum of the longitudinal and torsional shears due to the factored loads in the concrete deck per connector shall not exceed Q_r determined from Eq. 6.10.10.4.1-1.

distribution provisions for straight box sections had shear connectors throughout the negative flexure region.

Maximum flexural and torsional shears are typically not produced by concurrent loads. However, the interaction between flexure and torsion due to moving loads is too complex to treat practically. Instead, for cases where the torsional shear must be considered, these provisions allow the longitudinal shear range for fatigue to be computed from Eq. 6.10.10.1.2-4 using the sum of the maximum flexural and torsional shears in the web subjected to additive shears. The shear range and the resulting pitch should be computed using one-half the moment of inertia of the composite box section. The top flange over the other web, or the other half of the flange for a closed-box section, should contain an equal number of shear connectors. Because of the inherent conservatism of these requirements, the radial fatigue shear range due to curvature need not be included when computing the horizontal fatigue shear range for box sections in either straight or horizontally curved spans or segments.

Shear connectors on box flanges are best distributed uniformly across the flange width to ensure composite action of the entire flange with the concrete. The shear connectors are to be spaced transversely to satisfy Eq. 6.11.10-1 in order to help prevent local buckling of the flange plate when subject to compression. The torsional shear or shear range resisted by the concrete deck can be determined by multiplying the torsional shear or shear range acting on the top of the composite box section by the ratio of the thickness of the transformed concrete deck to the total thickness of the top flange plus the transformed deck. Adequate transverse reinforcement should be provided in the deck to resist this torsional shear.

6.11.11—Web Stiffeners

Transverse intermediate web stiffeners shall be designed according to the provisions of Article 6.10.11.1.

Longitudinal web stiffeners shall be designed according to the provisions of Article 6.10.11.3.

Except as specified herein, bearing stiffeners shall be designed according to the provisions of Article 6.10.11.2. Bearing stiffeners should be attached to diaphragms rather than inclined webs. For bearing stiffeners attached to diaphragms, the provisions of Article 6.10.11.2.4b shall apply to the diaphragm rather than to the web. At expansion bearings, bearing stiffeners and diaphragms should be designed for eccentricity due to thermal movement.

6.12—MISCELLANEOUS FLEXURAL MEMBERS

6.12.1—General

6.12.1.1—Scope

The provisions of this Article shall apply to:

- noncomposite H-shaped members bent about either axis of the cross-section, and noncomposite I-shaped members bent about their weak axis;
- noncomposite single-cell rectangular box-section members with or without longitudinal stiffeners, including square and rectangular HSS, bent about either principal axis;
- noncomposite circular tubes, including round HSS;
- channels, angles, tees, rectangular bars, and solid rounds;
- concrete-encased rolled shapes; and
- circular concrete-filled steel tubes (CFSTs).

6.12.1.2—Strength Limit State

6.12.1.2.1—Flexure

At the strength limit state, the section shall satisfy:

$$M_{+} \leq M_{-} \quad (6.12.1.2.1-1)$$

C6.11.11

When inclined webs are used, bearing stiffeners should be attached to either an internal or external diaphragm rather than to the webs so that the bearing stiffeners are perpendicular to the sole plate. Thermal movements of the bridge may cause the diaphragm to be eccentric with respect to the bearings. This eccentricity should be recognized in the design of the diaphragm and bearing stiffeners. The effects of the eccentricity are usually most critical when the bearing stiffeners are attached to diaphragms. The effects of the eccentricity can be recognized by designing the bearing stiffener assembly as a beam-column according to the provisions of Articles 6.10.11.2 and 6.9.2.2.

C6.12.1.1

This Article covers miscellaneous rolled or built-up noncomposite or composite members subject to flexure, often in combination with axial loads; that is, flexural members not covered by the provisions of Article 6.10 or 6.11. Included are doubly- and singly symmetric noncomposite single-cell rectangular box-section members with or without longitudinal stiffeners, and with cross-section principal axes parallel to the cross-section component plates. These sections are often utilized in trusses, frames, and arches. In addition, angles, tees, and channels are addressed. These sections are often utilized as cross-frame, diaphragm, and lateral bracing members.

Noncomposite circular tubes or pipes may be designed using the provisions specified herein for round HSS, provided that they conform to ASTM A53/A53M, Grade B and the appropriate parameters are used in the design. Additional information on connection design for square, rectangular, and round HSS may be found in Chapter K of AISC (2022b). Resistances for fatigue design for square, rectangular and round HSS may be found in Section 10.2.3 of the ANSI/AWS D1.1/D1.1M *Structural Welding Code—Steel* or in Section 11 of the *AASHTO LRFD Specifications for Structural Supports for Highway Signs, Luminaries and Traffic Signals*. Where these members are used in NSTM applications, refer to Article 8.2.3 of the *AASHTO LRFD Guide Specifications for the Design of Pedestrian Bridges* (2014).

Except as specified herein, the factored flexural resistance, M_r , shall be taken as:

$$M_r = \phi_f M_n \quad (6.12.1.2.1-2)$$

where:

ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2

M_n = nominal flexural resistance of the section, determined as specified in Articles 6.12.2.2 and 6.12.2.3 for noncomposite and composite members, respectively (kip-in.)

M_u = factored bending moment about the axis of bending under consideration (kip-in.)

The material-based P-M interaction curve of composite circular CFSTs shall be determined as specified in Article 6.12.2.3.3.

6.12.1.2.2—Combined Flexure, Axial Load, and Flexural and/or Torsional Shear

C6.12.1.2.2

The provisions of Article 6.8.2.3 for combined axial tension, flexure, and flexural and/or torsional shear, or the provisions of Article 6.9.2.2 for combined axial compression, flexure, and flexural and/or torsional shear shall apply, as applicable.

For noncomposite circular tubes, including round HSS, that are subject to combined flexure, axial load, and flexural and/or torsional shear, Eq. 6.12.1.2.3a-5 shall be checked in addition to the interaction of the flexural or torsional shear resistances with the member axial and flexural resistances as specified in Articles 6.8.2.3.2 or 6.9.2.2.2, as applicable.

These provisions assume low or zero levels of axial force in the member and uniaxial flexure. For members that are also subject to a factored concentrically applied axial force, P_u , in excess of 5 percent of the factored axial resistance of the member, P_r or P_{ry} as applicable, at the strength limit state, and/or if the member is subject to biaxial bending, the member should instead be checked according to the provisions of Article 6.8.2.3 or 6.9.2.2, as applicable. The level of 5 percent is based conservatively on the linear interaction equations given in these articles, which apply in the majority of cases. Below this level, it is reasonable to ignore the effect of the axial force in the design of the member.

6.12.1.2.3—Flexural Shear and/or Torsion

6.12.1.2.3a—General

C6.12.1.2.3a

At the strength limit state, the section shall satisfy:

$$V_u \leq V_r \quad (6.12.1.2.3a-1)$$

The factored flexural shear resistance, V_r , shall be taken as:

$$V_r = \phi_v V_n \quad (6.12.1.2.3a-2)$$

At the strength limit state, noncomposite circular tubes, including round HSS, subject to torsion only shall satisfy:

$$T_u \leq T_r \quad (6.12.1.2.3a-3)$$

These provisions are used to check the factored flexural shear resistance of the web elements of noncomposite rectangular box-section members, including square and rectangular HSS, webs of composite members and other noncomposite members covered by the provisions of Article 6.12, noncomposite circular tubes, including round HSS, and concrete-filled tubes, including CFSTs, that are subject to flexural shear only.

These provisions are also used to check the factored torsional resistance of noncomposite circular tubes, including round HSS, that are subject to torsion only, or the resistance of such members that are subject to combined flexural shear and torsion.

The factored torsional resistance, T_r , of noncomposite circular tubes, including round HSS, shall be taken as:

$$T_r = \phi_T T_n \quad (6.12.1.2.3a-4)$$

where:

ϕ_T = resistance factor for torsion, specified in Article 6.5.4.2

ϕ_v = resistance factor for shear, specified in Article 6.5.4.2

T_n = nominal torsional resistance for noncomposite circular tubes and round HSS (kip-in.), calculated as specified in Article 6.12.1.2.3b

T_u = factored torque at the section under consideration (kip-in.)

V_n = nominal flexural shear resistance (kip) calculated as follows:

- For each web element of a noncomposite rectangular box-section member, including square and rectangular HSS, the provisions of Articles 6.10.9 and 6.12.1.2.4 shall apply, as applicable.
 - In checking Eq. 6.10.9.3.2-1, b_{fc} shall be taken as one-half the effective width between webs determined as specified in Article 6.9.4.2.2b for longitudinally unstiffened compression flanges with F_{cr} taken equal to F_{yc} , and as one-half the effective area between webs determined as specified in Article 6.12.2.2d, including the longitudinal stiffeners, divided by the thickness of the plate for longitudinally stiffened compression flanges. b_{ft} shall be taken as one-half the gross area of the tension flange, including any longitudinal stiffeners, divided by the thickness of the plate. Shear lag effects shall be considered, as applicable, in the determination of b_{fc} and b_{ft} , as specified in Article 6.12.2.2g.
- For noncomposite circular tubes, including round HSS, the provisions of Article 6.12.1.2.3b shall apply.
- For webs of all other noncomposite members, the provisions of Article 6.10.9 shall apply, as applicable.
- For webs of composite members and for concrete-filled tubes, including composite circular CFSTs, the provisions of Article 6.12.3 shall apply, as applicable.

V_u = for noncomposite circular tubes, including round HSS, factored flexural shear at the section under consideration. For noncomposite rectangular box-section members subject to

torsion, including square and rectangular HSS, the factored shear in each web element shall be taken as the sum of the flexural and St. Venant torsional shears (kip)

For noncomposite circular tubes, including round HSS, subject to both flexural shear and torsion, the following relationship shall be satisfied at the strength limit state:

$$\frac{V_u}{V_r} + \frac{T_u}{T_r} \leq 1.0 \quad (6.12.1.2.3a-5)$$

For stems of tees and for elements of noncomposite I- and H-shapes loaded about their weak axis, the shear buckling coefficient, k , shall be taken as 1.2.

6.12.1.2.3b—Circular Tubes and Round HSS

For noncomposite circular tubes, including round HSS, the nominal flexural shear resistance, V_n , shall be taken as:

$$V_n = 0.5 F_{cr} A_g \quad (6.12.1.2.3b-1)$$

in which:

F_{cr} = flexural shear buckling resistance (ksi) taken as the larger of either:

$$F_{cr1} = \frac{1.60E}{\sqrt{L_v \left(\frac{D}{t} \right)^4}} \leq 0.58F_y \quad (6.12.1.2.3b-2)$$

or:

$$F_{cr2} = \frac{0.78E}{\left(\frac{D}{t} \right)^2} \leq 0.58F_y \quad (6.12.1.2.3b-3)$$

where:

- A_g = gross area of the section based on the design wall thickness (in.)
- D = outside diameter of the tube (in.)
- L_v = distance between points of maximum and zero shear, or the full length of the member if the shear does not go to zero within the member length (in.)
- t = wall thickness of the tube (in.). For round HSS, the provisions of Article 6.12.1.2.4 shall apply.

The nominal torsional resistance, T_n , shall be taken as:

$$T_n = F_{cv} C \quad (6.12.1.2.3b-4)$$

C6.12.1.2.3b

The provisions for noncomposite circular tubes, including round HSS, subject to flexural shear are based on the provisions for local buckling of cylinders due to torsion. However, since torsion is generally constant along the member length and flexural shear typically has a gradient, the critical buckling stress for flexural shear is taken as 1.3 times the critical stress for torsion (Brockenbrough and Johnston, 1981) (Ziemian, 2010). The torsional shear equations apply over the full length of the member, but for flexural shear, it is reasonable to use the length between points of maximum and zero shear. The nominal flexural shear resistance is computed assuming that the shear stress at the neutral axis is at F_{cr} . The resulting stress at the neutral axis is $V/\pi R t$, in which the denominator is half the area of the circular tube.

in which:

$$C = \text{torsional constant (in.}^3\text{)}$$

$$= \frac{\pi (D - t)^2 t}{2} \quad (6.12.1.2.3b-5)$$

F_{cr} = torsional shear buckling resistance (ksi) taken as the larger of either:

$$F_{cv1} = \frac{1.23E}{\sqrt{\frac{L}{D} \left(\frac{D}{t}\right)^4}} \leq 0.58F_y \quad (6.12.1.2.3b-6)$$

or:

$$F_{cv2} = \frac{0.60E}{\left(\frac{D}{t}\right)^2} \leq 0.58F_y \quad (6.12.1.2.3b-7)$$

where:

L = length of the member (in.)

6.12.1.2.4—Special Provisions for Hollow Structural Section Members

For square and rectangular hollow structural section members, the web depth, D , shall be taken as the clear distance between flanges less the inside corner radius on each side, and the area of both webs shall be considered effective in resisting the shear.

For square and rectangular hollow structural section members, the inside width of each flange, b_{fi} , shall be taken as the clear width of the flange between the webs less the inside corner radius on each side.

For square, rectangular, and round hollow structural section members, the design wall thickness, t , shall be taken as the nominal wall thickness for HSS produced according to ASTM A1085/A1085M. For HSS produced according to other standards specified in Article 6.4.1, t shall be taken as 0.93 times the nominal wall thickness.

C6.12.1.2.4

These provisions are used to define the web depth, D , and inside flange width, b_{fi} , for the design of square and rectangular hollow structural section members, and the design wall thickness, t , for the design of square, rectangular, and round hollow structural section members. These provisions are referred to in Articles 6.9.4.2, 6.12.1.2.3, 6.12.2.2.2, and 6.12.2.2.3.

For square and rectangular hollow structural section members, if the inside corner radius is not known, use the outside dimension minus three times the appropriate design wall thickness specified herein.

6.12.2—Nominal Flexural Resistance

6.12.2.1—General

Provisions for LTB need not be applied to composite members, noncomposite I- and H-shaped members bent about their weak axis, and noncomposite circular tubes.

6.12.2.2—Noncomposite Members*6.12.2.2.1—I- and H-Shaped Members**C6.12.2.2.1**6.12.2.2.1a—General**C6.12.2.2.1a*

The provisions of this Article apply to I- and H-shaped members and members consisting of two channel flanges connected by a web plate subject to flexure about their weak axis.

The provisions of Article 6.10 shall apply to flexure about an axis perpendicular to the web.

The nominal flexural resistance, M_n , for flexure about the weak axis shall be taken as the smaller value based on yielding or FLB, as specified in Articles 6.12.2.2.1b and 6.12.2.2.1c, respectively.

The equations in this Article are based on the equations given in Section F6 of AISC (2022b). I- and H-shaped members bent about their weak axis do not experience LTB or web local buckling; the only limit states to be considered are yielding and FLB.

*6.12.2.2.1b—Yielding**C6.12.2.2.1b*

The nominal flexural resistance based on yielding shall be taken as:

$$M_n = M_p = F_y Z_y \leq 1.6 F_y S_y \quad (6.12.2.2.1b-1)$$

where:

- F_y = specified minimum yield strength (ksi)
- M_p = plastic moment about the weak axis (kip-in.)
- S_y = elastic section modulus about the weak axis (in.³)
- Z_y = plastic section modulus about the weak axis (in.³)

The limit of $1.6 F_y S_y$ in Eq. 6.12.2.2.1b-1 is intended to ensure against substantial early yielding in channels subjected to weak axis bending, potentially leading to inelastic response under service conditions. The weak-axis plastic moment capacity of I-sections rarely exceeds this limit. For H-shaped members, M_p about the weak axis is equal to $1.5 F_y S_y$.

6.12.2.2.1c—FLB

The nominal flexural resistance based on FLB shall be taken as:

- If $\lambda_f \leq \lambda_{pf}$, then FLB shall not apply.
- If $\lambda_{pf} < \lambda_f \leq \lambda_{rf}$, then:

$$M_n = M_p - \left(M_p - 0.7 F_y S_y \right) \left(\frac{\lambda_f - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \quad (6.12.2.2.1c-1)$$

- If $\lambda_f > \lambda_{rf}$, then:

$$M_n = \frac{0.69 E S_y}{\lambda_f^2} \quad (6.12.2.2.1c-2)$$

in which:

- λ_f = slenderness ratio for the flange

$$= \frac{b_f}{2t_f} \quad (6.12.2.2.1c-3)$$

λ_{pf} = limiting slenderness ratio for a compact flange

$$= 0.38 \sqrt{\frac{E}{F_{yf}}} \quad (6.12.2.2.1c-4)$$

λ_{nf} = limiting slenderness ratio for a noncompact flange

$$= 1.0 \sqrt{\frac{E}{F_{yf}}} \quad (6.12.2.2.1c-5)$$

where:

b_f = flange width (in.)

F_{yf} = specified minimum yield strength of the lower-strength flange (ksi)

M_p = plastic moment about the weak axis (kip-in.)

S_y = elastic section modulus about the weak axis (in.³)

t_f = flange thickness (in.)

6.12.2.2.2—Rectangular Box-Section Members

6.12.2.2.2a—General

For doubly- and singly symmetric single-cell rectangular box-section members with or without longitudinal stiffeners, bent about either principal axis, the nominal flexural resistance shall be based on the combined influence of general yielding, compression FLB, and/or LTB. The nominal flexural resistance corresponding to these limit states shall be determined as specified in Article 6.12.2.2.2e. In addition, for all box-section members, the provisions of Article 6.12.2.2.2f shall be considered at the fatigue and service limit states, and for constructability.

For box sections with different thickness webs, the smaller web thickness shall be used in the calculation of all section properties.

Sections designed according to these provisions shall satisfy the cross-section proportion limits specified in Article 6.12.2.2.2b.

C6.12.2.2.2a

Article 6.12.2.2.2 addresses the flexural design of homogeneous and hybrid doubly- and singly symmetric single-cell rectangular box-section members with or without longitudinal stiffeners, including square and rectangular HSS, bent about either principal axis in which the cross-section principal axes are parallel to the cross-section component plates.

The concepts and procedures specified in Article 6.12.2.2.2 for rectangular box-section members are also largely applicable to other noncomposite box cross-section profiles, including trapezoidal geometries, parallelogram geometries, which can be found in tie members of basket-handle arches, and octagonal or other geometries, which may be used in large steel box-section towers. White et al. (2019b) discuss the extension of these provisions to the design of members with general box cross-section profiles.

AISC Design Guide 25 (White et al., 2021a) provides broad guidelines for the design of general nonprismatic I-section members. The concepts employed in these provisions and guidelines also may be employed to extend the provisions of Article 6.12.2.2.2 for calculation of the design resistance of general nonprismatic box-section members. Article D6.6 of these Specifications captures the application of these procedures to nonprismatic I-section flexural members.

For sections subjected to flexure only, if there are holes in the tension flange at the section under consideration, the tension flange shall satisfy the provisions of Article 6.10.1.8, with f_t taken as the factored stress on the gross area of the tension flange. For sections with holes in a tension flange subjected to flexure combined with axial tension or compression, the provisions of Article 6.8.2.3.3 shall apply. Access holes within a flange of a box-section member shall satisfy the provisions of Article 6.11.1.4.

For noncomposite box-section members subject to torsion, transverse plate bending stresses due to cross-section distortion should be considered for fatigue and at the strength limit state. The factored transverse plate bending stresses should not exceed 20.0 ksi at the strength limit state. Longitudinal warping stresses due to cross-section distortion should be considered for fatigue, but may be ignored at the strength limit state. Transverse plate bending and longitudinal warping stresses due to cross-section distortion shall be determined by rational structural analysis. Transverse stiffeners attached to the webs or flanges should be considered effective with the web or flange in resisting transverse plate bending.

Internal diaphragms and cross-frames for noncomposite box-section members shall satisfy the provisions of Article 6.7.4.4.

Any box-section member component plate subjected to stress due to bending about a principal axis of the box parallel to the plate is considered as a flange for bending about that axis. Any component plate subjected to flexural shear orthogonal to the axis of bending, and/or nominally linearly varying normal stresses due to bending about an axis normal to the face of the plate, is considered as a web. Generally, a given box-section component plate may serve as a flange for bending about one principal axis and as a web for bending about the other principal axis.

Where an access hole or perforation is provided in a flange, the hole should be deducted in determining the gross section for checking the requirements of Article 6.10.1.8 or 6.8.2.3.3.

Article 6.11.1.4 provides broad guidelines for the design of access holes, ventilation, and drainage in composite box-section flexural members. These provisions also are generally applicable for noncomposite rectangular box-section members. Additional considerations are necessary for the assessment of the resistance to combined axial tension or compression, flexure and/or torsion at such cross-sections.

Bent caps should be detailed to facilitate maintenance and inspection access. Access holes should be provided at the ends, or if necessary, on the top of these members.

In certain types of box-section members, access holes or other large holes may be placed in one of the webs. AISC Design Guide 2 (Darwin, 1990) provides broad design guidelines that may be adapted for the design of box-section members with large web holes.

Transverse plate bending stresses in flanges and webs of box-section members subject to torsion occur due to changes in direction of the shear-flow vector and are associated with distortion of the box cross-section profile. Most rectangular box sections are capable of resisting torsion with limited distortion of the cross-section. Distortion is generally limited by providing sufficient internal bracing in accordance with the provisions of Article 6.7.4.4; as such, torsion is mainly resisted by St. Venant torsional shear flow. In addition, the warping constant is approximately equal to zero for rectangular box sections. Thus, warping shear and normal stresses due to warping torsion are typically quite small and are usually neglected. For typical welded noncomposite box-section members subject to large torques, further investigation of the cross-section distortional stresses may be warranted, particularly for fatigue investigations. Article C6.11.1.1 discusses the use of the beam-on-elastic foundation or BEF analogy (Wright and Abdel-Samad, 1968a) for the determination of cross-section distortional stresses and stress ranges.

Bearing stiffeners shall be designed according to the provisions of Article 6.10.11.2. Bearing stiffeners should be attached to diaphragms. At expansion bearings, bearing stiffeners and diaphragms should be designed for eccentricity due to thermal movement.

The provisions of Article 6.12.2.2.2g shall be considered to account for shear lag effects, as applicable.

6.12.2.2.2b—Cross-Section Proportion Limits

Webs without longitudinal stiffeners shall be proportioned such that:

$$\frac{D}{t_c} \leq 150 \quad (6.12.2.2.2b-1)$$

where:

- D = for welded box sections, the clear distance between the flanges. For HSS, the provisions of Article 6.12.1.2.4 shall apply (in.)
- t_w = thickness of the webs (in.). For box sections with different thickness webs, the smaller web thickness. For HSS, the provisions of Article 6.12.1.2.4 shall apply.

Webs with longitudinal stiffeners shall be proportioned such that:

$$\frac{D}{t_w} \leq 300 \quad (6.12.2.2.2b-2)$$

Web longitudinal stiffeners shall satisfy the provisions of Article 6.10.11.3.

Longitudinally unstiffened compression and tension flanges should be proportioned such that:

$$b_{\beta} / t_f \leq 90 \quad (6.12.2.2b-3)$$

where:

- b_{fi} = inside width of the box section flanges (in.); for welded box sections, the clear width of the flange under consideration between the webs.

Thermal movements of the member may cause the diaphragm to be eccentric with respect to the bearing. This eccentricity should be recognized in the design of the diaphragm and bearing stiffeners. The effects of the eccentricity can be recognized by designing the bearing stiffener assembly as a beam-column according to the provisions of Articles 6.10.11.2 and 6.9.2.2.

Flowcharts illustrating the application of the provisions of Article 6.12.2.2.2 for determining the flexural resistance of rectangular noncomposite box-section members, with or without longitudinally stiffened plates, are provided in Article C6.5.2 in Appendix C6.

C6.12.2.2.2b

Article 6.12.2.2b specifies a number of broad not-to-exceed or not-to-be-smaller-than limits on the proportions of box-section members. Various specific design criteria may require dimensions that are more restrictive than these maximum or minimum limits.

Eq. 6.12.2.2.2b-1 is a practical upper limit on the slenderness of webs without longitudinal stiffeners expressed in terms of the web depth, D . By limiting the slenderness of transversely stiffened webs to this value, the web shear resistance may be increased by providing transverse stiffeners up to a maximum spacing of $3D$. In addition, this is a conservative limit on the slenderness of longitudinally unstiffened webs to avoid potential distortion-induced fatigue considerations.

For mechanically fastened built-up box-section members, b_f and D in these provisions should be taken as the distance between the outer lines of fasteners connecting the component plate elements. It is recommended that the pitch of the fasteners in the compression and tension flanges satisfy the maximum pitch requirements for stitch bolts in compression members and tension members, respectively, specified in Article 6.13.2.6.3.

The upper limit given by Eq. 6.12.2.2.2b-2 parallels the upper limit for longitudinally stiffened webs of I-girders specified in Article 6.10.2.1.2.

Plates subjected to significant uniform compression stresses at the fatigue and/or service limit states, or during construction, will tend to be limited to b_{pl}/t_{fc} significantly less than 90 or w/t_f less than 90, as applicable, and D/t_w less than 150 or 300, as applicable, by the provisions of Article 6.12.2.2.2f.

The limits of $b_{ff}/t_f \leq 90$, $w/t_f \leq 90$ and $t_f \geq 0.5$ in. are recommended to limit potential local deformation or distortion of box section flanges during fabrication, transportation, erection, and service conditions. Flanges violating these limits may have out-of-plane plate

For HSS, the provisions of Article 6.12.1.2.4 shall apply.

t_f = thickness of the flange under consideration (in.).
For HSS, the provisions of Article 6.12.1.2.4 shall apply.

The thickness of the compression and tension flanges corresponding to the box section principal axis subjected to the larger bending moment should not be less than the thickness of the webs. The thickness of compression and tension flanges shall not be less than 0.5 in., unless otherwise specified by the Owner.

Sections with a longitudinally unstiffened compression flange shall be classified for flexural design as specified in Article 6.12.2.2.2c.

Compression flanges exceeding the limit given by Eq. 6.12.2.2.2b-3 shall include longitudinal stiffeners. Tension flanges with b_f/t_f exceeding 130 shall include longitudinal stiffeners. Longitudinally stiffened flanges should be proportioned such that:

$$w / t_f \leq 90 \quad (6.12.2.2.2b-4)$$

where:

w = widths of the flange plate between the centerlines of the individual longitudinal stiffeners and/or between the centerline of a longitudinal stiffener and the inside of the laterally restrained longitudinal edge of a longitudinally stiffened plate element (in.)

Sections with a longitudinally stiffened compression flange shall be classified for flexural design as specified in Article 6.12.2.2.2d. Flange longitudinal stiffeners shall satisfy the provisions of Article E6.1.4. Transverse stiffeners, when utilized to strengthen or stiffen a longitudinally stiffened flange, shall satisfy the requirements of Article E6.1.5.

deflections approaching a significant fraction of $b_f/300$ or $w/300$ under their self-weight plus a transverse concentrated load of 300 lbs., which is considered by ASCE/SEI 7-16 (ASCE, 2016) as a visible deflection limit. These limits also help alleviate significant buckling distortion due to welding residual stresses resulting in oil canning and waviness of the flange, and the amplification of these distortions by small unintended axial compressive and/or shear stresses under service conditions, such as shifting of true inflection point locations from nominal positions calculated in the design (White et al., 2019a).

For box sections with b_f/t_f or w/t_f of the flange plates greater than 100, some noticeable buckling distortion of the flange plate may occur during fabrication due to minimal welding of the flange plate to the webs and/or welding of any stiffeners to the flange plate. In addition, the nominal resistance of compression flanges is relatively small as b_f/t_f or w/t_f exceeds 100. Box flanges with b_f/t_f or w/t_f values larger than about 130 will have difficulty maintaining the $b_f/300$ or $w/300$ out-of-plane deflection under self-weight, or under self-weight with a small concentrated transverse load; therefore, plate out-of-plane sagging due to these nominal loads may be noticeable.

The flange thicknesses corresponding to the box section principal axis direction with the largest bending moment should not be smaller than the corresponding web thicknesses. As such, the plate bending stresses due to distortion of the box section under torsional loads will tend to be larger in the webs than in the flange.

For welded box sections, a minimum thickness of 0.75 in. is recommended for component plates subjected to significant stress due to bending about a cross-section axis parallel to the plates. This suggested minimum thickness is intended to ensure robustness and resiliency of the member response, to facilitate handling, and to minimize distortion and possible cupping of the plates during welding. An absolute minimum thickness of 0.5 in. is specified, unless otherwise permitted by the Owner, to avoid increasing sensitivity to welding distortions and deflections under self-weight and small concentrated applied loads. Smaller thicknesses are common, however, for box-section members employed in long-span bridge construction, where the expense associated with handling and control of distortion in thin stiffened plates is justified by the savings in weight.

In cases where a longitudinally stiffened flange plate acts as a web in one of the directions of bending, the requirement to include transverse stiffeners at a maximum spacing of $2D$ specified in Article 6.10.11.1.1 may be waived unless a transverse stiffener spacing less than $2D$ is employed in the calculation of the shear buckling resistance of the plate, and the requirements of Article 6.10.11.3 for proportioning the longitudinal stiffeners may be waived unless the longitudinal stiffeners are considered in the calculation of R_b in Article 6.10.1.10.2. The longitudinal stiffeners may be

The outside width of the box section shall satisfy:

$$b_{fo} \geq D/6 \quad (6.12.2.2.2b-5)$$

where:

b_{fo} = outside width of the box section taken as the distance from the outside to the outside of the box-section webs (in.)

Flange extensions on compression flanges of box sections shall be proportioned such that:

$$b/t_f \leq 0.38 \sqrt{\frac{E}{F_y}} \quad (6.12.2.2.2b-6)$$

where:

b = clear projecting width of the compression flange under consideration measured from the outside surface of the web (in.)

t_f = thickness of the flange under consideration (in.)

6.12.2.2.2c—Classification of Sections with a Longitudinally Unstiffened Compression Flange

Sections with a longitudinally unstiffened compression flange that satisfy:

$$\lambda_w \leq \lambda_{pw} \quad (6.12.2.2.2c-1)$$

shall qualify as compact web sections, in which:

λ_w = web slenderness

$$= \frac{2D_{ce}}{t_w} \quad (6.12.2.2.2c-2)$$

λ_{pw} = limiting slenderness ratio for a compact web

$$= 3.1 \left(\frac{D_{ce}}{D_{cpe}} \right) \sqrt{\frac{E}{F_{yc}}} \quad (6.12.2.2.2c-3)$$

For a compact web section,

included in the calculation of gross cross-section properties regardless of the satisfaction of the maximum spacing requirement of 2D.

In cases where a longitudinally stiffened flange plate acts as a web in one direction of bending, and includes transverse stiffeners, the requirements of Article 6.10.11.1 may be waived provided that the transverse stiffeners are not considered in the calculation of the web flexural shear resistance in Article 6.10.9.

D/6 is a minimum limit for the outside width of box-section members. There are no HSS with widths smaller than this limit, and smaller widths in welded box sections would necessitate the potential consideration of elastic LTB in the provisions contained herein.

Eq. 6.12.2.2.2b-6 limits the width-to-thickness ratio of compression flange extensions in box sections such that these components are not subject to any strength reduction associated with local buckling under flexural and/or axial compression. As such, the full gross width of the extensions, measured from the outside surface of the box section webs, may be employed in the calculation of the effective and gross box-section properties.

C6.12.2.2.2c

Articles 6.12.2.2.2c and 6.12.2.2.2d provide the classification of a comprehensive range of rectangular box-section profiles based on the web and compression flange slenderness, and define the cross-section based parameters R_b , R_{pc} , R_f and M_{yce} employed for calculation of box-section member resistances in Article 6.12.2.2.2e. Depending on the classification of the box section under consideration, the parameters R_b , R_{pc} , and/or R_f may be taken simply equal to 1.0, and M_{yce} may be taken equal to the fundamental yield moment of the gross cross-section, to the compression flange, $M_{yc} = S_{xc}F_y$. Typical box sections only require a limited number of the equations provided in Articles 6.12.2.2.2c and 6.12.2.2.2d.

Eq. 6.12.2.2.2c-1 ensures that the section is able to develop the full plastic moment resistance on the effective cross-section, M_{pe} , provided that lateral-torsional bracing requirements are satisfied. Such cross-sections are referred to as compact web sections. The limiting web slenderness ratio, λ_{pw} , is somewhat larger than the value specified for doubly symmetric

$$R_{pc} = \frac{M_{pe}}{M_{yce}} \quad (6.12.2.2c-4)$$

where:

- D_{ce} = depth of the web in compression in the elastic range, considering early nominal yielding in tension when $S_{ste} < S_{xce}$, and using the effective box cross-section based on the effective width of the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} ; for welded sections, depth from the inside of the compression flange; for HSS, the provisions of Article 6.12.1.2.4 shall apply (in.)
- D_{cpe} = depth of the web in compression at the plastic moment determined using the effective box cross-section based on the effective width of the compression flange; for welded sections, depth from the inside of the compression flange; for HSS, the provisions of Article 6.12.1.2.4 shall apply (in.)
- F_{yc} = specified minimum yield strength of the compression flange (ksi)
- I_{xe} = effective moment of inertia of the cross-section about the axis of bending determined using the effective width for the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} , and the gross area for the tension flange (in.⁴). Except as specified in Article 6.12.2.2d, any web and/or tension flange longitudinal stiffeners should be included in the calculation of I_{xe}
- M_{pe} = plastic moment using the effective box cross-section based on the effective width of the compression flange (kip-in.)
- M_{yce} = yield moment with respect to the compression flange taken as $F_{yc}S_{xce}$ (kip-in.) for sections in which $S_{ste} \geq S_{xce}$, and calculated as the moment at nominal first yielding of the compression flange, considering early nominal yielding in tension, for sections in which $S_{ste} < S_{xce}$
- R_{pc} = web plastification factor for the compression flange
- S_{xce} = effective elastic section modulus about the axis of bending to the compression flange determined using the effective width for the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} , and the gross area for the tension flange (in.³). Except as specified in Article 6.12.2.2d, any web and/or tension flange longitudinal stiffeners should be included in the calculation of S_{xce} . The effective elastic section modulus, S_{xce} shall be determined by dividing the effective moment of inertia, I_{xe} , by the distance to the corresponding extreme fibers of the cross-section.
- S_{ste} = effective elastic section modulus about the axis of bending to the tension flange determined

noncomposite box sections in AISC (2022b), and is slightly larger than the Class 2 limit for noncomposite box sections specified in CEN (2005), which is intended to ensure that the plastic moment of the cross-section can be developed, contingent on the satisfaction of other plate slenderness and member unbraced length requirements necessary to develop the plastic moment. For a compact web section, the web plastification factor given by Eq. 6.12.2.2c-4 is the shape factor of the effective cross-section.

The coefficient 3.1 in Eq. 6.12.2.2c-3 can be explained in part by considering the comparable compact web limit defined for general I-section members, Eq. A6.2.1-2, which is illustrated in Figure CA6.2.1-1. The form of Eq. A6.2.1-2 corresponding to $2D_c/t_w$, Eq. A6.2.2-8, appears in Table B4.1 of AISC (2022b). For I-sections with $M_p/R_hM_y = 1.12$, Eq. A6.2.1-2 gives a coefficient of 3.77, which is essentially the coefficient corresponding to the compact web limit specified in Eq. 6.10.6.2.2-1. This coefficient is a reasonable median value for rolled I-section members and welded doubly symmetric I-section members with comparable proportions. However, for I-sections with $M_p/R_hM_y = 1.21$, Eq. A6.2.1-2 gives a coefficient of 3.1. The ratio $M_p/R_hM_y = 1.21$ is more representative of box-section members with webs proportioned near the compact limit. In addition, the coefficient 3.1 in Eq. 6.12.2.2c-3 reflects the restraint conditions provided to the webs by the flanges in box-section members. The use of the ratio (D_{ce}/D_{cpe}) in Eq. 6.12.2.2c-3 is similar to the use of (D_c/D_{cp}) in Eq. A6.2.2-8. This ratio converts the compact web limit to a value that corresponds to a consistent definition of the web slenderness of $2D_{ce}/t_w$ which is employed with the web compact and noncompact limits in defining the web plastification factor, R_{pc} , in Eq. 6.12.2.2c-7.

Eq. 6.12.2.2c-1 and the subsequent equations specified herein are expressed generally in terms of the effective cross-section, considering the post-buckling response of a slender compression flange. Box-section compression flanges, which are supported by webs along two longitudinal edges, have substantial post-buckling resistance. However, unlike I-section members, where the FLB resistance is limited to incipient theoretical FLB, an interaction exists between the post-buckling response of the compression flange and the other strength limit states of the member. This behavior is captured by the use of the effective cross-section, based on the effective width of the compression flange, in the calculation of D_{ce} , D_{cpe} , M_{yce} , and M_{pe} .

The calculations associated with Eqs. 6.12.2.2c-1 through 6.12.2.2c-4 and the subsequent calculations in Article 6.12.2.2c may be simplified as follows:

- For box sections in which the compression flange is compact, the effective width of the

using the effective width for the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} , and the gross area for the tension flange (in.^2). Except as specified in Article 6.12.2.2.2d, any web and/or tension flange longitudinal stiffeners should be included in the calculation of S_{xte} . The effective elastic section modulus, S_{xte} , shall be determined by dividing the effective moment of inertia, I_{xe} , by the distance to the corresponding extreme fibers of the cross-section.

t_w = web thickness (in.); for box sections with different thickness webs, the smaller web thickness; for HSS, the provisions of Article 6.12.1.2.4 shall apply.

For compact web sections, the web load-shedding factor, R_b , shall be taken as 1.0.

compression flange is equal to its gross width, and thus the calculations in Article 6.12.2.2.2c are all based on the gross box cross-section. Otherwise, the calculations in Article 6.12.2.2.2c are based on the effective section, using the effective width of the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} .

- For HSS with slender flange elements, the calculation of the effective section modulus, S_{xce} , the corresponding yield moment, M_{yce} , the plastic depth of web in compression, D_{cpe} , and the effective plastic moment, M_{pes} , may be determined in a manner that parallels the recommended calculation of the effective area for axial compression for these types of sections for Eq. 6.9.4.2.2a-4. For example, the effective section modulus may be calculated as:

$$S_{xce} = S_x - \frac{(b - b_e)t_f^3 / 12 + (b - b_e)t_f c_c^2}{c} \quad (\text{C6.12.2.2.2c-1})$$

where:

- c_c = distance from the neutral axis of the effective cross-section to the mid-thickness of the rectangular portion of the compression flange area, considering the effective width of the slender flange and using the gross cross-section for the web (in.)
- c = distance from the neutral axis of the effective cross-section to the extreme fiber of the compression flange (in.)

This avoids complications in the consideration of the corners of HSS. Other variables in Eq. C6.12.2.2.2c-1 are defined in Articles 6.12.2.2.2c and 6.9.4.2.2a.

- For doubly symmetric box-section members, a conservative estimate of the nominal flexural resistance may be obtained by using the effective width for both the compression and the tension flange in the calculation of the effective section properties. This maintains symmetry of the cross-section and thus simplifies the calculations. For singly symmetric box-section members, the shift in the neutral axis should be accounted for in the calculation of the effective section properties.

The limit state of tension-flange yielding does not apply to box-section members with a longitudinally unstiffened compression flange. Instead, in cases where $S_{xte} < S_{xce}$, early nominal yielding in tension is to be considered in the calculation of D_{ce} and M_{yce} . Figure C6.12.2.2.2c-1 illustrates the stress state corresponding to these variables for a hybrid cross-section with a

compression flange having an effective width less than its actual width, indicated by the black shaded area in the figure. For a homogeneous cross-section, F_{yf} is equal to F_{yw} , giving the stress distribution represented by the light grey lines if the flexural strain distribution were the same as in the hybrid case. For a homogeneous cross-section, the following closed-form expression for the depth of the web in compression is obtained based on a rigorous strain compatibility analysis:

Figure C6.12.2.2c-1—Illustration of the Stress State Corresponding to D_{ce} and M_{yce} in a Box Section where $S_{ste} < S_{sce}$, Considering the Early Nominal Yielding that Occurs First at the Tension Flange

$$D_{ce} = \frac{\Delta A + \sqrt{\Delta A^2 + 2A_{fce}A_{wfc} - A_{wfc}^2}}{8t_w} - t_{fc} \quad (\text{C6.12.2.2c-2})$$

in which:

$$\Delta A = A_{ft} + A_w + A_{wfc} - A_{fce} \quad (\text{C6.12.2.2c-3})$$

$$A_{fce} = b_{fce} t_{fc} \quad (\text{C6.12.2.2c-4})$$

$$A_{ft} = b_{ft} t_{ft} \quad (\text{C6.12.2.2c-5})$$

$$A_w = 2D t_w \quad (\text{C6.12.2.2c-6})$$

$$A_{wfc} = 4t_{fc} t_w \quad (\text{C6.12.2.2c-7})$$

where:

- b_{fce} = effective width of the compression flange, including corners and flange extensions (in.)
- b_{ft} = width of the tension flange, including the corners and flange extensions (in.)
- D = depth of the web (in.)

Sections with a longitudinally unstiffened compression flange that satisfy:

$$\lambda_{pw} < \lambda_w \leq \lambda_{rw} \quad (6.12.2.2.2c-5)$$

shall qualify as noncompact web sections,

in which:

$$\begin{aligned} \lambda_{rw} &= \text{limiting slenderness ratio for a noncompact web} \\ &= 4.6 \sqrt{\frac{E}{F_{yc}}} \end{aligned} \quad (6.12.2.2.2c-6)$$

For a noncompact web section:

$$R_{pc} = \left[1 - \left(1 - \frac{R_h M_{yce}}{M_{pe}} \right) \left(\frac{\lambda_w - \lambda_{pw}}{\lambda_{rw} - \lambda_{pw}} \right) \right] \frac{M_{pe}}{M_{yce}} \leq \frac{M_{pe}}{M_{yce}} \quad (6.12.2.2.2c-7)$$

For noncompact web sections, the web load-shedding factor, R_b , shall be taken as 1.0.

Sections with a longitudinally unstiffened compression flange that satisfy:

$$\lambda_w > \lambda_{rw} \quad (6.12.2.2.2c-8)$$

shall qualify as slender web sections.

For a slender web section, the following shall apply:

- The web plastification factor, R_{pc} , shall be taken as 1.0 for a homogeneous section and as R_h for a hybrid section.
- The web load-shedding factor, R_b , shall be determined using the applicable provisions of

inelastic strains necessary to develop yielding throughout the depth of the cross-section. Any enhancement of the resistance of compact or noncompact web sections due to the placement of web longitudinal stiffeners subjected to compression, other than the increase in M_{yce} , is neglected in these provisions. The section may be classified according to the web slenderness as specified in Articles 6.12.2.2.2c and 6.12.2.2.2d, as applicable, without considering the web longitudinal stiffeners. Web longitudinal stiffeners should be included in the calculation of the elastic gross and effective cross-section properties. In general, these cross-section elements provide a small but measurable contribution to the elastic cross-section properties and to the effective yield moment values. To be included in the calculation of the section properties, the longitudinal stiffener must be structurally continuous at the ends of interior web panels. At end panels or member ends, the longitudinal stiffener should be structurally continuous at one end and positively attached to the diaphragm at the other end.

Eq. 6.12.2.2.2c-6 defines the slenderness limit for a box-section noncompact web. This limit assumes simply supported boundary conditions at the web-flange juncture, and is the same as the limit given by Eq. 6.10.6.2.3-1 for I-sections in cases where the area of the I-section flanges is small relative to the web area. This limit is slightly larger than the Class 3 limit for noncomposite box sections specified in CEN (2005), which is intended to ensure that the yield moment of the cross-section can be developed, contingent on the satisfaction of other necessary plate slenderness and unbraced length requirement. Webs with a slenderness ratio exceeding this limit are termed slender. Sections with slender webs may rely upon significant web post bend-buckling resistance at the strength limit state.

For noncompact web sections, Eq. 6.12.2.2.2c-7 accounts for the influence of the web slenderness on the nominal flexural resistance. As the value of $2D_{ce}/t_w$ approaches the noncompact web slenderness limit, λ_{rw} , the maximum potential value of the nominal flexural resistance—commonly referred to as the plateau strength—approaches $R_f R_h M_{yce}$. Eq. 6.12.2.2.2c-7 defines a web plastification factor that provides a smooth transition in the plateau strength from $R_f R_h M_{yce}$ to $R_f M_{pe}$ as $2D_{ce}/t_w$ varies from λ_{rw} to the compact web slenderness limit.

The plateau strength of a slender web section is $R_b R_f R_h M_{yce}$; the term R_b is discussed below.

Several simplifications may be applied for the slender web member calculations in many cases:

- The term, R_{pc} , simplifies to R_h for a slender-web hybrid box section;
- The term, R_{pc} , simplifies to 1.0 for a slender-web homogeneous box section, and;

Article 6.10.1.10.2. In applying the provisions of Article 6.10.1.10.2, a_{wc} shall be determined with $b_{fc}t_{fc}$ taken as one-half of the flange area for a compact flange section, and as one-half of the effective flange area, $b_{efc}/2$, for a noncompact or slender flange section, including corners and flange extensions; D_c shall be taken as the depth of the web in compression using the effective cross-section, D_{ce} , and; for sections having webs of different thickness, t_w shall be taken as the smaller web thickness. The effective width of the flange, b_e , shall be determined as specified in Article 6.9.4.2.2b, with the value of F_{cr} taken equal to F_y .

- The term, R_{pc} , simplifies to 1.0 for a slender-web homogeneous box section, and;
- The term, R_f , simplifies to 1.0 and M_{yc} simplifies to M_{yc} if the box section has a compact flange.

Furthermore, the slender web box-section provisions may be applied conservatively, with R_b taken equal to 1.0, for any noncompact- or compact-web box section.

For compact and noncompact web sections, theoretical web bend-buckling does not occur for moment levels up to the limit of the flexural resistance. Therefore, the web load-shedding factor, R_b , is simply equal to 1.0 for these sections. For sections containing a compact compression flange and a compact web, the Article 6.12.2.2.2e plateau resistance $R_b R_{pc} R_f M_{yc}$ is simply equal to M_p . For slender web sections, R_b is to be calculated as specified herein to account for the reduction in the section flexural resistance caused by the shedding of stresses to the compression flange due to bend-buckling of the slender web.

For members with one or more longitudinal web stiffeners placed at d_s/D_{ce} approaching 0.76 or larger, where d_s is the distance from the centerline of the closest longitudinal stiffener to the inner surface of the compression flange, the value of R_b determined from the provisions of Article 6.10.1.10.2 tends to be relatively small since these provisions neglect the impact of web longitudinal stiffeners on the web bend-buckling response for $d_s/D_{ce} \geq 0.76$. These proportions are common in some types of columns and arch ribs. In addition, in narrow box sections, the value of a_{wc} employed in the calculation of R_b can be relatively large. The R_b equation tends to be conservative in these situations. In these cases, a larger plateau strength may be determined by using a strain compatibility analysis considering an effective width of the longitudinally stiffened webs, as discussed in Lokhande and White (2018).

For noncompact web and slender web sections, the following shall apply in the determination of the hybrid factor, R_h :

- For noncompact web and slender web sections with $S_{xte} \geq S_{xcs}$, the hybrid factor, R_h , shall be determined using the provisions of Article 6.10.1.10.1.
- For noncompact web and slender web sections with $S_{xte} < S_{xcs}$, the hybrid web stress state may be considered directly in the calculation of M_{yc} in lieu of calculating R_h using Article 6.10.1.10.1. In this case R_h shall be taken equal to 1.0.
- In the calculation of R_h using the provisions of Article 6.10.1.10.1, for cross-sections in which D_n is the distance from the elastic neutral axis to the compression flange, the value of A_{fn} shall be taken as one-half of the total compression flange

area for a compact flange section, and as one-half of the total effective compression flange area for a noncompact or slender flange section, including corners and flange extensions; for cross-sections in which D_n is the distance from the elastic neutral axis to the tension flange, the value of A_{fn} shall be taken as one-half the total tension flange area, including corners and flange extensions; for box sections having webs of different thickness, t_w shall be taken as the smaller web thickness.

Sections with a longitudinally unstiffened compression flange that satisfy:

$$\lambda_f \leq \lambda_{pf} \quad (6.12.2.2.2c-9)$$

shall qualify as compact flange sections,

in which:

$$\begin{aligned} \lambda_f &= \text{compression flange slenderness} \\ &= \frac{b_{fi}}{t_{fc}} \quad (6.12.2.2.2c-10) \end{aligned}$$

where:

- λ_{pf} = limiting slenderness ratio for a compact flange, taken as the value of λ_r specified in Table 6.9.4.2.1-1 for the type of flange under consideration
- b_{fi} = inside width of the box section flanges(in.); for welded box sections, clear width of the compression flange between the webs. For HSS, the provisions of Article 6.12.1.2.4 shall apply
- t_{fc} = thickness of the compression flange (in.). For HSS, the provisions of Article 6.12.1.2.4 shall apply

For compact flange sections:

$$R_f = 1.0 \quad (6.12.2.2.2c-11)$$

where:

$$R_f = \text{compression flange slenderness factor}$$

Sections with a longitudinally unstiffened compression flange that satisfy:

$$\lambda_{pf} < \lambda_f \leq \lambda_{rf} \quad (6.12.2.2.2c-12)$$

shall qualify as noncompact flange sections,

in which:

Box-section flanges that satisfy the nonslender limit in uniform axial compression specified in Article 6.9.4.2.1 are defined herein as compact. For welded built-up box sections, λ_{pf} as specified by these provisions is comparable to the compact flange limit in AISC (2022b), and it is comparable to the Class 1 flange limit in CEN (2005), which is intended to ensure that the section can form a plastic hinge with a rotation capacity sufficient for plastic analysis, contingent on the satisfaction of other necessary plate slenderness and unbraced length requirements. This more restrictive limit is also related to the shift in Winter's classical plate effective width curve for welded built-up box sections discussed in Article C6.9.4.2.2b. For cold-formed HSS, λ_{pf} as specified by these provisions is comparable to the Class 2 flange limit in CEN (2005), which is intended to ensure that the plastic moment of the cross-section can be developed, contingent on the satisfaction of other plate slenderness and member unbraced length requirements necessary to develop the plastic moment. For nonwelded built-up box sections and hot-formed HSS, λ_{pf} as specified by these provisions is slightly larger than the Class 2 flange limit in CEN (2005).

Box-section members with longitudinally unstiffened compression flanges traditionally classified in the AISC and AASHTO provisions as noncompact are Capable of developing a flexural resistance close to the cross-section full plastic moment, M_p , if the webs are compact according to the classifications specified herein and the member is adequately braced (Lokhande and White, 2018). Box sections with a compression flange slenderness larger than the compact flange limit given by

$$\begin{aligned}\lambda_{rf} &= \text{limiting slenderness ratio for a noncompact flange} \\ &= 1.56\lambda_{pf}\end{aligned}\quad (6.12.2.2c-13)$$

For a noncompact flange section:

$$R_f = \left[1 - 0.15 \left(\frac{\lambda_f - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \right] \leq 1.0 \quad (6.12.2.2c-14)$$

Sections with a longitudinally unstiffened compression flange that satisfy:

$$\lambda_f > \lambda_{rf} \quad (6.12.2.2c-15)$$

shall qualify as slender flange sections.

For a slender flange section:

$$R_f = 0.85 \quad (6.12.2.2c-16)$$

6.12.2.2d—Classification of Sections with a Longitudinally Stiffened Compression Flange

Sections with a longitudinally stiffened compression flange shall be classified as slender web sections.

For the purpose of calculating the yield moment of the effective cross-section with respect to the compression flange, the longitudinally stiffened compression flange shall be represented by the following effective area located at the centroid of the gross area of the entire flange plate and its longitudinal stiffeners:

$$A_{eff} = P_{nsp} / F_{yc} \quad (6.12.2.2d-1)$$

Eq. 6.12.2.2c-9 have a compression flange effective width smaller than the gross width of the flange, as well as a compression flange slenderness factor, R_f , smaller than 1.0.

The compression flange slenderness factor, R_f , accounts for reductions in the plateau strength of noncompact and slender flange box sections due to the limited ability of these types of flanges (1) to develop the inelastic strains necessary to achieve yielding through the depth of the cross-section, and (2) to accept the stresses shed to them due to bend-buckling of a slender web. These reductions are in addition to the reductions associated with the compression flange effective width as well as the web-based parameters, R_b and R_{pc} . Lokhande and White (2018) found that the reductions in the flexural resistance of these types of box-section members is represented with good accuracy by Eqs. 6.12.2.2c-12 through 6.12.2.2c-16.

For compact-flange box sections, the term R_f is taken simply equal to 1.0.

C6.12.2.2d

Longitudinally stiffened box-section compression flanges are generally unable to withstand inelastic deformations necessary to develop significant yielding throughout the depth of the box section webs without significant reductions in their compressive resistance. Hence, the largest possible flexural resistance of these types of members is limited to the effective yield moment, M_{yce} , which corresponds to the development of the maximum compressive resistance of the longitudinally stiffened compression flange. As such, box sections with longitudinally stiffened compression flanges are in effect handled as slender web sections.

In cases where flange longitudinal stiffeners are provided but are not required for strength, the longitudinal stiffeners may be neglected and the flange may be considered as longitudinally unstiffened for purposes of calculating the member resistance. However, all requirements pertaining to the longitudinal stiffeners must be satisfied for such sections.

The limit state of tension-flange yielding does not apply to box section members with a longitudinally stiffened compression flange. Instead, in cases where $S_{xtc} < S_{xces}$, early nominal yielding in tension is to be considered in the calculation of D_{ce} and M_{yce} . Figure C6.12.2.2c-1 illustrates the stress state corresponding to these variables for a hybrid cross-section with a longitudinally unstiffened compression

where:

- P_{nsp} = nominal compressive resistance of the compression flange calculated as specified in Article E6.1.3 (kip)
- F_{yc} = specified minimum specified yield strength of the longitudinally stiffened compression flange (ksi)

The effective elastic section moduli, S_{xce} and S_{xte} , shall be determined by dividing the effective moment of inertia, I_{xe} , by the distance to the corresponding extreme fiber of the cross-section, where I_{xe} is calculated as specified in Article 6.12.2.2.2c using the effective area, A_{eff} , in lieu of the effective width, b_e , for the compression flange.

For sections with a longitudinally stiffened compression flange and with $S_{xte} \geq S_{xce}$, D_{ce} shall be determined based on the effective elastic cross-section and the nominal yield moment to the compression flange shall be calculated as $M_{yce} = F_{yc}S_{xce}$.

For sections with a longitudinally stiffened compression flange and with $S_{xte} < S_{xce}$, M_{yce} shall be calculated as the moment at nominal first yielding of the effective compression flange, considering early nominal yielding in tension, and the depth of the web in compression for the effective section, D_{ce} , shall be calculated accordingly based on this stress state.

For sections with a longitudinally stiffened compression flange, the following shall apply:

- The compression flange slenderness factor, R_f , shall be taken equal to 1.0.
- The web plastification factor, R_{pc} , shall be taken equal to 1.0 for homogeneous sections, and as R_h determined using the provisions of Article 6.10.1.10.1 for hybrid sections with $S_{xte} \geq S_{xce}$.
- In the calculation of R_h using the provisions of Article 6.10.1.10.1, when D_n is the distance from the elastic neutral axis to the compression flange, A_{fn} shall be taken as $A_{eff}/2$, including corners and flange extensions; when D_n is the distance from the elastic neutral axis to the tension flange, A_{fn} shall be taken as one-half the total tension-flange area including corners, flange extensions, and any longitudinal

flange. For a homogeneous cross-section, F_{yf} is equal to F_{yw} . In lieu of a more rigorous strain compatibility analysis, this idealized model, and the corresponding equations in Article C6.12.2.2.2c, may be employed for calculating the D_{ce} and M_{yce} of a box section with a longitudinally stiffened compression flange by: (1) substituting the effective compression flange area, A_{eff} , determined using Eq. 6.12.2.2.2d-1, for A_{fce} ; (2) modeling the effective compression flange area as a zero-thickness strip located at the centroid of the gross compression flange area including the longitudinal stiffeners; (3) taking t_{fc} as zero inches in the last term of Eq. C6.12.2.2.2c-2; (4) taking the web depth as the depth between the effective compression flange elevation and the elevation of a zero-thickness strip representing the tension-flange area and located at the centroid of the tension flange; and (5) neglecting any web longitudinal stiffeners.

When applying Eq. C6.12.2.2.2c-2 to a box section with a longitudinally stiffened flange, if a negative value of D_{ce} is obtained, the effective compression flange is relatively large. In this case, the neutral axis of the cross-section corresponding to the nominal first yielding of the idealized zero-thickness strip representing the compression flange is located at the centroid of the effective compression flange. For this extreme case, the strains at the compression flange will be relatively small and essentially the entire cross-section below the compression flange will be yielded in tension at the onset of nominal first yielding of the compression flange. Therefore, M_{yce} may be taken equal to the plastic moment of the effective cross-section, M_{pe} , for this case. The inelastic deformation of the compression flange needed to develop this flexural resistance is relatively small and can be accommodated by the longitudinally stiffened compression flange. Also, the webs of the box section are loaded entirely in tension at the onset of nominal first yielding of the compression flange, and therefore web local buckling is not a consideration.

R_f is simply taken equal to 1.0 in sections with longitudinally stiffened compression flanges; the calculation of the effective area of the compression flange quantifies the flexural resistance of these types of box-section members accurately to conservatively without any further reduction (Lokhande and White, 2018).

stiffeners; for sections having webs of different thickness, t_w shall be taken as the smaller web thickness. For hybrid sections in which $S_{yte} < S_{yce}$, the hybrid web stress state may be considered directly in the calculation of M_{yce} in lieu of calculating R_h using Article 6.10.1.10.1. In this case, R_h shall be taken equal to 1.0.

- The web load-shedding factor, R_b , shall be determined using the applicable provisions of Article 6.10.1.10.2. In applying the provisions of Article 6.10.1.10.2, a_{wc} shall be determined with $b_{fc}t_{fc}$ taken as $A_{eff}/2$; the value of D_c shall be taken as the depth of the web in compression using the effective cross-section, D_{ce} , and; for sections having webs of different thickness, the value of t_w shall be taken as the smaller web thickness.

Except as specified herein, the areas of all longitudinal stiffeners should be included in the calculation of the elastic gross and effective cross-section properties. In cases in which the webs have different longitudinal stiffening, or in which only one web has longitudinal stiffeners, the longitudinal stiffeners should not be included.

6.12.2.2.2e—General Yielding, Compression FLB and LTB

The nominal flexural resistance based on the combined influence of general yielding, compression FLB and LTB shall be determined as follows:

- If $L_b \leq L_p$, then:

$$M_n = R_f R_b R_{pc} M_{yce} \quad (6.12.2.2.2e-1)$$

- Otherwise:

$$M_n = C_b R_b \left[R_{pc} R_f M_{yce} - (R_{pc} R_f M_{yce} - F_{yr} S_{xyc}) \left(\frac{L_b - L_p}{L_r - L_p} \right) \right] \leq R_b R_{pc} R_f M_{yce} \quad (6.12.2.2.2e-2)$$

in which:

J = St. Venant torsional constant of the gross cross-section (in.⁴)

$$= \frac{4A_o^2}{\sum \frac{b_m^3}{t}} \quad (6.12.2.2.2e-3)$$

L_p = limiting unbraced length to achieve the nominal flexural resistance $R_f R_b R_{pc} M_{yce}$ under uniform moment (in.)

C6.12.2.2.2e

Eqs. 6.12.2.2.2e-1 and 6.12.2.2.2e-2 quantify the nominal flexural resistance considering the combined effects of general yielding, compression FLB, and LTB. For longitudinally unstiffened box sections satisfying the cross-section proportion limits of Article 6.12.2.2.2b, the limiting unbraced length L_p for members with $D/b_{fo} < 2.0$ is always larger than $6D$. In addition, the limiting unbraced length L_r for these types of members is commonly larger than $70D$. As such, the reduction in the flexural resistance under uniform bending is never more than approximately 10 percent for longitudinally unstiffened box-section members with $D/b_{fo} < 2.0$ and $L_b/D < 20$ that satisfy the cross-section proportion limits of Article 6.12.2.2.2b. The maximum reduction in the flexural resistance under uniform bending is approximately one-half of this value, i.e., 5 percent, for members with $D/b_{fo} \leq 2.0$ and $L_b/D \leq 10$. Members that have stocky compression and tension flanges combined with webs proportioned at the maximum limit of Eq. 6.12.2.2.2b-1 exhibit the largest reduction in strength associated with the LTB limit state. In designs where the moment-gradient modifier C_b is greater than 1.10, this reduction is nonexistent.

For longitudinally stiffened box sections satisfying the cross-section proportion limits of Article 6.12.2.2.2b, the limiting unbraced length L_p for members with $D/b_{fo} \leq 2.0$ is always larger than $4D$. In addition, the limiting unbraced length L_r for these types of members is commonly larger than $50D$. As such, the reduction in the

$$= 0.10E_r \frac{\sqrt{JA}}{M_{yce}} \quad (6.12.2.2.2e-4)$$

L_r = limiting unbraced length for calculation of the LTB resistance (in.)

$$= 0.60E_r \frac{\sqrt{JA}}{F_{yr} S_{xce}} \quad (6.12.2.2.2e-5)$$

$$b_m = b_{fo} - t_w \quad (6.12.2.2.2e-6)$$

where:

A = gross cross-sectional area of the box section, including any longitudinal stiffeners (in.²)

A_o = cross-sectional area enclosed by the mid-thickness of the walls of the box-section member (in.²)

b_{fo} = outside width of the box section taken as the distance from the outside to the outside of the box-section webs (in.)

b_m = gross width of each plate of the box-section member taken between the mid-thickness of the adjacent plates (in.)

C_b = moment-gradient modifier, determined as specified in Article A6.3.3.1

F_{yc} = specified minimum yield strength of the compression flange (ksi)

F_{yr} = compression-flange stress at the onset of nominal yielding within the cross-section, including residual stress effects, for moment applied about the axis of bending, taken as $0.5F_{yc}$ (ksi)

I_{xe} = effective moment of inertia of the cross-section about the axis of bending determined using the effective width for the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} , or using the effective area for the compression flange, A_{eff} , calculated as specified in Article 6.12.2.2.2d, as applicable, and the gross area for the tension flange (in.⁴). Except as specified in Article 6.12.2.2.2d, any web and/or tension flange longitudinal stiffeners should be included in the calculation of I_{xe} .

L_b = unbraced length (in.)

M_{yce} = yield moment of the effective cross-section with respect to the compression flange calculated as specified in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable (kip-in.)

R_f = compression flange slenderness factor, determined as specified in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable

R_b = web load-shedding factor, determined as specified in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable

R_{pc} = web plastification factor for the compression flange, determined as specified in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable

flexural resistance under uniform bending is never more than approximately 20 percent for members with $D/b_{fo} \leq 2.0$ and $L_b/D \leq 20$ that satisfy the cross-section proportion limits of Article 6.12.2.2.2b. The maximum reduction in the flexural resistance under uniform bending is approximately one-half of this value, i.e., 10 percent, for members with $D/b_{fo} \leq 2.0$ and $L_b/D \leq 10$. Members that have stocky compression and tension flanges combined with webs proportioned at the maximum limit of Eq. 6.12.2.2.2b-1 exhibit the largest reduction in strength associated with the LTB limit state. In designs where the moment-gradient modifier, C_b , is greater than 1.20, this reduction is nonexistent.

The limiting unbraced length, L_r , is commonly larger than the largest practical unbraced length, taken as the smaller of $30D$ and $200r_y$, for all box sections satisfying the cross-section proportion limits of Article 6.12.2.2.2b. Therefore, elastic LTB need not be considered for all practical noncomposite box section members. Eq. 6.12.2.2.2e-2 may be employed to calculate the resistance for any extreme situations where $L_b > L_r$.

L_p given by Eq. 6.12.2.2.2e-4 is the same as the corresponding limiting length for box sections given in the corresponding AISC (2022b) provisions with the exception that the plastic moment, M_p , is estimated as $1.3M_{yce}$. The bracing requirements to reach the LTB plateau strength given by Eq. 6.12.2.2.2e-1 are comparable for all types of box-section members, irrespective of whether the cross-section is capable of developing the plastic moment M_p or not (Lokhande and White, 2018). For general box-section members, it may be stated that Eq. 6.12.2.2.2e-4 is based on the theoretical length corresponding to an elastic LTB resistance of $(1.3)(15)M_{yce} = 20M_{yce}$. Therefore, as a general rule, if the elastic LTB load is greater than $20M_{yce}$, the box-section member may be checked solely for its plateau strength in flexure. The parameters F_{yr} and L_r in this Article differ from the corresponding AISC provisions. These parameters have been determined based on test simulation studies conducted by Lokhande and White (2018), as well as consideration of the LTB resistance predictions of other standards such as CEN (2006). The limiting length, L_r , is taken as approximately 30 percent of the limiting length corresponding to theoretical elastic LTB at a compression-flange stress equal to F_{yr} .

Eqs. 6.12.2.2.2e-4 and 6.12.2.2.2e-5 are derived from the fundamental equations for elastic LTB of doubly symmetric rectangular box-section members. Lokhande and White (2018) show similar equations based on the rigorous theoretical elastic LTB of singly symmetric box-section members. The corresponding LTB resistance predictions using the rigorously derived equations for singly symmetric box-section members are never more than 1 percent different from the predictions obtained by simply applying the doubly symmetric section based equations specified herein to singly symmetric section members. The maximum change in the limiting unbraced length, L_p , obtained by using the equations herein, versus

- r_y = radius of the gyration of the gross box section about its minor principal axis, including any longitudinal stiffeners (in.⁴)
- S_{xce} = effective elastic section modulus about the axis of bending to the compression flange determined using the effective width for the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} , or using the effective area for the compression flange, A_{eff} , calculated as specified in Article 6.12.2.2.2d, as applicable and the gross area for the tension flange; the effective elastic section modulus, S_{xce} shall be determined by dividing the effective moment of inertia, I_{xe} , by the distance to the corresponding extreme fibers of the actual cross-section (in.³)
- t = thickness of each plate of the box-section member (in.)

6.12.2.2.2f—Service and Fatigue Limit States and Constructibility

Box-section webs shall satisfy the provisions of Article 6.10.3.3 for constructibility and the special fatigue requirement specified in Article 6.10.5.3.

the rigorously derived equations for singly symmetric box-section members, is approximately 10 percent. The maximum change in the limiting unbraced length, L_r , obtained by using the equations herein versus the rigorously derived equations for singly symmetric box-section members, is less than 1 percent. Therefore, the much simpler L_p and L_r equations derived assuming doubly symmetric cross-sections are specified to address all types of rectangular box-section members in these provisions.

It should be emphasized that the calculations in this Article based on the underlying elastic LTB equations always use the gross cross-section properties. These are combined with the use of the effective cross-section properties for all terms related to the yield or plastic moment resistance of the cross-section.

C6.12.2.2.2f

The provisions of Article 6.10.3.3 investigate the webs for the shear due to the factored load for constructibility specified in Article 3.4.2.1. The nominal shear resistance for this check is limited to the shear yielding or shear buckling resistance, V_{cr} . The use of tension-field action is not permitted under this load during construction.

The provisions of Article 6.10.5.3 are intended to alleviate any significant elastic flexing of the webs due to shearing actions under the unfactored permanent load plus the Fatigue I load combination. The shear is also limited in this case to V_{cr} to ensure that the member is able to sustain an infinite number of loadings without fatigue cracking due to this effect.

For box-section members subject to torsion, web shear yielding or shear buckling should be checked according to the provisions of Articles 6.10.3.3 and 6.10.5.3 for the critical web subjected to additive flexural and torsional shear. Shear yielding or shear buckling of the flange plates in box-section members need not be checked because the flange torsional shears are generally small at these limit states and such a check is unlikely to control. Also, flange shear stresses due to flexure, which are tangent to the wall of the flange plate, are maximum at the connection to the webs, zero at a location within the middle of the plate, and the net shear force in the flanges is zero.

Web longitudinal stiffeners are ignored in the calculation of the web shear yielding or shear buckling resistance, V_{cr} .

The provisions of Article 6.9.4.5 also shall be satisfied for the applicable plates within the cross-section, at the service limit state and for constructibility, when one or more of the following conditions are applicable:

- The section is a slender web section as defined in Article 6.12.2.2.2c;
- The section contains slender longitudinally stiffened plate panels, as defined in Article E6.1.2;
- The slenderness, λ_{fs} , of a longitudinally unstiffened compression flange exceeds λ_{pf} , as defined in Article 6.12.2.2.2c.

The flanges of noncomposite box-section members also shall satisfy the following requirement at the service limit state:

$$f_f \leq 0.80 R_h F_{yf} \quad (6.12.2.2.2f-1)$$

where:

- f_f = flange stress due to overall flexure of the box-section member under Service II loads (ksi)
 F_{yf} = specified minimum yield strength of the flange (ksi)
 R_h = hybrid factor determined as specified in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable

6.12.2.2.2g—Flange Effective Width or Area Accounting for Shear Lag Effects

C6.12.2.2.2g

To account for shear lag effects in the calculation of the flexural resistance at the strength limit state, in lieu of a more rigorous analysis, where a box-section member has an effective span, L_{eff} , less than $5b_{fi}$, the following quantities shall be multiplied by:

$$(L_{eff}/5)/b_{fi} \leq 1.0 \quad (6.12.2.2.2g-1)$$

- The effective area, b_{eff} , of a longitudinally unstiffened compression flange, with b_e determined as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_y , or;
- The effective area, A_{eff} , of a longitudinally stiffened compression flange determined as specified in Article 6.12.2.2.2d, and;
- The gross area of the tension flange including any longitudinal stiffeners,

where:

Since post-buckling resistance is assumed at the strength limit state in computing the nominal flexural resistance of box-section members with slender webs, box sections containing slender longitudinally stiffened plate panels, sections with a noncompact or slender longitudinally unstiffened compression flange, such members must also satisfy the provisions of Article 6.9.4.5 to ensure that plate local buckling due to flexural stresses does not occur theoretically at the service limit state and for constructibility. Plate local buckling is not checked at the fatigue limit state in Article 6.9.4.5 because the plate buckling check under the Service II loads will tend to control over a similar check under the unfactored permanent load plus the Fatigue I load combination.

For box-section members subjected to combined axial and flexural stresses, Article 6.9.4.5 checks plate local buckling directly for the combined stress state.

This Article provides simplified rules requiring the consideration of shear lag effects only for cases where the effective span, L_{eff} , is less than $5b_{fi}$, with the exception of the calculation of elastic flexural stresses under service and fatigue limit states and for constructibility within cantilevers and within the negative moment regions of continuous-span members. In many practical situations, there is no reduction in the flange effective width due to shear lag. The reductions in flange effectiveness due to shear lag are more significant for cantilevers and negative moment regions at these limit states. Where required, the reductions on the compression flange effective area, b_{eff} , the compression flange effective area, A_{eff} , and the tension flange gross area, as applicable, are applied in a simplified manner as a uniform reduction for all the cross-sections within the effective span of the member under consideration. These reductions are employed only for the purpose of determining cross-section resistances at the strength limit states, or cross-section stresses at the service and fatigue limit states and for constructibility. They are not intended as reductions to be applied within the bridge structural analysis.

- b_{fi} = inside width of the box section flanges (in.); for welded box sections, the clear width of the flange under consideration between the webs. For HSS, the provisions of Article 6.12.1.2.4 shall apply.
- L_{eff} = effective span taken as the span length for simple spans (in.); the distance between points of permanent load contraflexure, or between a simple support and a point of permanent load contraflexure, as applicable, for continuous spans; and two times the length from the support to the location of zero moment for cantilever spans.
- t_f = thickness of the flange under consideration (in.). For HSS, the provisions of Article 6.12.1.2.4 shall apply.

The centroid of the reduced flange areas, where any reduction applies, shall be taken as the centroidal location of the flange area prior to applying the reduction.

To account for shear lag effects in the calculation of elastic flexural stresses at the service and fatigue limit states and for constructibility, in lieu of a more rigorous analysis, the following shall apply:

- Within the negative moment regions of continuous-span members, and within cantilevers, in cases where L_{eff} is less than $30b_{fi}$, the reduction factor given by Eq. 6.12.2.2.2g-1 shall be replaced by the following:

- For $L_{eff} / b_{fi} \leq 15$:

$$\left[0.376 + 0.0542 \frac{L_{eff}}{b_{fi}} - 0.00156 \left(\frac{L_{eff}}{b_{fi}} \right)^2 \right] \leq \frac{(L_{eff} / 5)}{b_{fi}} \quad (6.12.2.2.2g-2)$$

- For $30 > L_{eff} / b_{fi} > 15$:

$$\left[0.697 + 0.00940 \frac{L_{eff}}{b_{fi}} \right] \leq 1.0 \quad (6.12.2.2.2g-3)$$

For longitudinally stiffened compression flanges, an additional factor of 0.9 shall be applied to Eq. 6.12.2.2.2g-2 or 6.12.2.2.2g-3, as applicable.

- For all other moment regions in cases where L_{eff} is less than $5b_{fi}$, the reduction factor given by Eq. 6.12.2.2.2g-1, shall apply.

6.12.2.2.3—Circular Tubes and Round HSS

For noncomposite circular tubes, including round HSS, the nominal flexural resistance shall be taken as the smaller value based on yielding or local buckling, as

For the consideration of shear lag effects at the strength limit state, the requirements specified herein are comparable to the Article 4.6.2.6.4 requirements specified for orthotropic steel decks, which recognize the benefits of inelastic redistribution of flange stresses. For the consideration of shear lag effects under service and fatigue limit states and for constructibility, the requirements specified herein also recognize that the reduction in the flange effectiveness in simple-span members and within the positive moment regions of continuous-span members tends to be relatively small, and may be neglected as a coarse approximation, as long as the flange width, b_{fi} , is below the $L_{eff}/5$ limit. However, the reduction in the elastic flange effectiveness for cantilevers and for negative moment regions of continuous spans tends to be more significant. Eqs. 6.12.2.2.2g-2 and 6.12.2.2.2g-3 are a fit to the curve provided by FHWA (1980) and Wolchuk (1997) for longitudinally unstiffened flanges, which is in turn based largely on the work by Moffatt and Dowling (1975, 1976). FHWA (1980) and Wolchuk (1997) recommend a reduction factor for longitudinally stiffened flanges that is up to 10 percent smaller than the value recommended for longitudinally unstiffened flanges. In lieu of a more refined calculation, it is specified that the values given by Eqs. 6.12.2.2.2g-2 and 6.12.2.2.2g-3 be multiplied by 0.9 for longitudinally stiffened flanges. White et al. (2019b) provide further discussion of the rationale for these curves. The requirements specified herein assume that flange extensions are sufficiently narrow such that they are fully effective with respect to shear lag, based on the compactness requirements of Eq. 6.12.2.2.2b-6. Positive and negative bending regions are defined herein based on the distance between the inflection points in positive or negative bending under the component dead load.

For special structures employing box-section members with unusually wide flanges compared to the effective span, the Engineer may wish to conduct refined analyses to obtain a more accurate accounting of shear lag effects. Full nonlinear analyses including the effect of residual stresses are necessary to capture the influence of inelastic stress redistribution on the flange effective widths at the strength limit state, which may be prohibitive for more routine bridge designs.

C6.12.2.2.3

Failure modes and post-buckling behavior of noncomposite circular tubes, including round HSS, can be grouped into the following three categories (Sherman,

applicable. The D/t of circular tubes used as flexural members shall not exceed $0.45E/F_y$.

For yielding, the nominal flexural resistance shall be taken as:

$$M_n = M_p = F_y Z \quad (6.12.2.2.3-1)$$

where:

- D = outside diameter of tube (in.)
- M_p = plastic moment (kip-in.)
- t = wall thickness of the tube (in.). For round HSS, the provisions of Article 6.12.1.2.4 shall apply.
- Z = plastic section modulus (in.³)

For sections where D/t is less than or equal to $0.07E/F_y$, the wall element of the section is defined as compact.

For sections where D/t exceeds $0.07E/F_y$, local buckling shall be checked. For local buckling, the nominal flexural resistance shall be taken as:

- If $\frac{D}{t} \leq \frac{0.31E}{F_y}$, then:

$$M_n = \left(\frac{0.021E}{\frac{D}{t}} + F_y \right) S \quad (6.12.2.2.3-2)$$

- If $\frac{D}{t} > \frac{0.31E}{F_y}$, then:

$$M_n = F_{cr} S \quad (6.12.2.2.3-3)$$

in which:

F_{cr} = elastic local buckling stress (ksi)

$$= \frac{0.33E}{\frac{D}{t}} \quad (6.12.2.2.3-4)$$

where:

S = elastic section modulus (in.³)

6.12.2.2.4—Tees and Double Angles

6.12.2.2.4a—General

For tees and double angles loaded in the plane of symmetry, the nominal flexural resistance shall be taken as the smallest value based on yielding, LTB, FLB, and local buckling of tee stems and double-angle web legs, as applicable.

1992) (Ziemian, 2010): 1) for D/t less than about $0.05E/F_y$, a long inelastic plateau occurs in the moment-rotation curve. The cross-section gradually ovalizes, then local wave buckles eventually form after which the flexural resistance slowly decays; 2) for $0.05E/F_y \leq D/t \leq 0.10E/F_y$, the plastic moment is nearly achieved but a single local buckle develops and the flexural resistance decays slowly with little or no inelastic plateau; and 3) for $D/t > 0.10E/F_y$, multiple buckles form suddenly with little ovalization and the flexural resistance drops rapidly to a more stable level. The specified flexural resistance equations reflect the above regions of behavior for sections with long constant moment regions and little restraint against ovalization at the failure location. The equations are based on five North American studies involving hot-formed seamless pipe, electric-resistance-welded pipe, and fabricated tubing (Sherman, 1992) (Ziemian, 2010).

C6.12.2.2.4a

The provisions for tees and double angles given herein are taken from AISC (2022b). The legs of double angles in continuous contact or with separators may together be assumed treated as the double-angle web legs in checking these provisions. The plane of symmetry is assumed to be that formed by their y -axis. For flexure of

6.12.2.2.4b—Yielding

For tee stems and double-angle web legs, the nominal flexural resistance based on yielding shall be taken as:

$$M_n = M_p \quad (6.12.2.2.4b-1)$$

in which:

- For tee stems and double-angle web legs subject to tension:

$$M_p = F_y Z_x \leq 1.6 M_y \quad (6.12.2.2.4b-2)$$

- For tee stems subject to compression:

$$M_p = M_y \quad (6.12.2.2.4b-3)$$

- For double-angle web legs subject to compression:

$$M_p = 1.5 M_y \quad (6.12.2.2.4b-4)$$

where:

- F_y = specified minimum yield strength (ksi)
 M_y = yield moment = $F_y S_x$ (kip-in.)
 S_x = elastic section modulus about the x -axis with respect to the tip of the tee stem or double-angle web legs (in.³)
 Z_x = plastic section modulus about the x -axis (in.³)

6.12.2.2.4c—LTB

For tee stems and double-angle web legs subject to tension, the nominal flexural resistance based on LTB shall be taken as:

- If $L_b \leq L_p$, then LTB shall not apply.

- If $L_p < L_b \leq L_r$, then:

$$M_n = M_p - (M_p - M_y) \left(\frac{L_b - L_p}{L_r - L_p} \right) \quad (6.12.2.2.4c-1)$$

- If $L_b > L_r$, then:

$$M_n = M_{cr} \quad (6.12.2.2.4c-2)$$

tees and double angles about the y -axis, which is considered to be a rare case in bridge applications, consult the Commentary to Section F9 of AISC (2022b).

C6.12.2.2.4b

The limit on M_p in Eq. 6.12.2.2.4b-2 of $1.6M_y$ for cases where the tee stem or double-angle web legs are in tension is intended to indirectly control situations where significant yielding of the stem or web legs may occur at service load levels. Similarly, M_p is limited to M_y in Eq. 6.12.2.2.4b-3 for cases where the tee stem is in compression, and to $1.5M_y$ in Eq. 6.12.2.2.4b-4 for cases where double-angle web legs are subject to compression.

C6.12.2.2.4c

Eq. 6.12.2.2.4c-5 is a simplified version of the elastic LTB equation developed in Kitipornchai and Trahair (1980) and discussed further in Ellifritt et al. (1992). For the case of tee stems and double-angle web legs subject to tension, i.e., when the flange is subject to compression, Eq. 6.12.2.2.4c-1 provides a linear transition from M_p , calculated from Eq. 6.12.2.2.4b-2, to the yield moment, M_y .

The moment-gradient modifier, C_b , specified for I-sections in Article 6.10.8.2.3b is not included in the equations of this Article as the application of C_b to cases where the stem is in compression is unconservative. Also, for reverse curvature bending, the portion with the stem in compression may govern the LTB resistance even though the corresponding moments may be small in relation to the moments in the other portions of the unbraced length. The LTB resistance for the case where

in which:

$$L_p = 1.76r_y \sqrt{\frac{E}{F_y}} \quad (6.12.2.2.4c-3)$$

$$L_r = 1.95 \left(\frac{E}{F_y} \right) \frac{\sqrt{I_y J}}{S_x} \sqrt{2.36 \left(\frac{F_y}{E} \right) \frac{d S_x}{J} + 1} \quad (6.12.2.2.4c-4)$$

$$M_{cr} = \frac{1.95E}{L_b} \sqrt{I_y J} \left(B + \sqrt{1 + B^2} \right) \quad (6.12.2.2.4c-5)$$

$$B = 2.3 \left(\frac{d}{L_b} \right) \sqrt{\frac{I_y}{J}} \quad (6.12.2.2.4c-6)$$

where:

- d = depth of the tee or width of the double-angle web leg in tension (in.)
- I_y = moment of inertia about the y -axis (in.⁴)
- J = St. Venant torsional constant (in.⁴)
- L_b = unbraced length (in.)
- r_y = radius of gyration about the y -axis (in.)
- S_x = elastic section modulus about the x -axis with respect to the tip of the tee stem or double-angle web legs (in.³)
- M_p = plastic moment = $F_y Z_x \leq 1.6 M_y$ (kip-in.)
- M_y = yield moment = $F_y S_x$ (kip-in.)
- Z_x = plastic section modulus about the x -axis (in.³)

For tee stems and double-angle web legs subject to compression anywhere along the unbraced length, the nominal flexural resistance based on LTB shall be taken as:

- For tee stems:

$$M_n = M_{cr} \leq M_y \quad (6.12.2.2.4c-7)$$

- For double-angle web legs:

- If $\frac{M_y}{M_{cr}} \leq 1.0$, then:

$$M_n = \left(1.92 - 1.17 \sqrt{\frac{M_y}{M_{cr}}} \right) M_y \leq 1.5 M_y \quad (6.12.2.2.4c-8)$$

- If $\frac{M_y}{M_{cr}} > 1.0$, then:

$$M_n = \left(0.92 - \frac{0.17 M_{cr}}{M_y} \right) M_{cr} \quad (6.12.2.2.4c-9)$$

in which:

the stem is in compression is substantially smaller than for the case where the stem is in tension. For cases where the stem is in tension, connection details should be designed to minimize end restraint moments that may cause the stem to be in flexural compression at the ends of the member.

For rolled sections, the St. Venant torsional constant, J , including the effect of the web-to-flange fillets, is tabulated in AISC (2023). For fabricated sections, Eq. A6.3.3-9 may be used with one of the flange terms removed.

$$B = -2.3 \left(\frac{d}{L_b} \right) \sqrt{\frac{I_y}{J}} \quad (6.12.2.2.4c-10)$$

where:

- d = depth of the tee or width of the double-angle web leg in compression (in.)
- M_{cr} = elastic LTB moment, determined from Eq. 6.12.2.2.4c-5 (kip-in.)
- M_y = yield moment = $F_y S_x$ (kip-in.)
- S_x = elastic section modulus about the x -axis with respect to the tip of the tee stem or double-angle web legs (in.³)

6.12.2.2.4d—FLB

For tee flanges subject to compression, the nominal flexural resistance based on FLB shall be taken as:

- If $\lambda_f \leq \lambda_{pf}$, then FLB shall not apply.
- If $\lambda_{pf} < \lambda_f \leq \lambda_{rf}$, then:

$$M_n = M_p - \left(M_p - 0.7 F_y S_{xc} \right) \left(\frac{\lambda_f - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \quad (6.12.2.2.4d-1)$$

- If $\lambda_f > \lambda_{rf}$, then:

$$M_n = \frac{0.7 E S_{xc}}{\left(\frac{b_f}{2 t_f} \right)^2} \quad (6.12.2.2.4d-2)$$

For double angles with the flange legs subject to compression, the nominal flexural resistance based on FLB shall be taken as:

- If $\lambda_f \leq \lambda_{pf}$, then FLB shall not apply.
- If $\lambda_{pf} < \lambda_f \leq \lambda_{rf}$, then:

$$M_n = F_y S_{xc} \left(2.43 - 1.72 \left(\frac{b_f}{t_f} \right) \sqrt{\frac{F_y}{E}} \right) \quad (6.12.2.2.4d-3)$$

- If $\lambda_f > \lambda_{rf}$, then:

$$M_n = \frac{0.7 E S_{xc}}{\left(\frac{b_f}{t_f} \right)^2} \quad (6.12.2.2.4d-4)$$

in which:

C6.12.2.2.4d

For cases where tee flanges or flange legs of double angles are in compression and λ_f does not exceed λ_{pf} , FLB does not control and need not be checked. Eq. 6.12.2.2.4d-1 represents an inelastic FLB resistance equation provided for tee flanges in AISC (2022b). Eq. 6.12.2.2.4d-3 represents a local buckling resistance equation provided for determining the inelastic local buckling resistance of single-angle legs in Section F10 of AISC (2022b), which is conservatively applied to determine the inelastic local buckling resistance of double angles with the flange legs subject to compression and loaded in the plane of symmetry as recommended in AISC (2022b). Elastic FLB resistance equations for cases with λ_f exceeding λ_{rf} , i.e., for slender flanges, are provided by Eqs. 6.12.2.2.4d-2 and 6.12.2.2.4d-4. The flanges of all rolled T-sections given in AISC (2022b) satisfy Eq. 6.10.2.2-1; therefore, this limit needs only be checked for fabricated T-sections.

λ_f = flange slenderness = $b_f/2t_f$ for tees and b_f/t_f for double angles

λ_{pf} = limiting slenderness for a compact flange

$$= 0.38 \sqrt{\frac{E}{F_y}} \text{ for tees} \quad (6.12.2.2.4d-5)$$

$$= 0.54 \sqrt{\frac{E}{F_y}} \text{ for double angles} \quad (6.12.2.2.4d-6)$$

λ_{rf} = limiting slenderness for a noncompact flange

$$= 1.0 \sqrt{\frac{E}{F_y}} \text{ for tees} \quad (6.12.2.2.4d-7)$$

$$= 0.91 \sqrt{\frac{E}{F_y}} \text{ for double angles} \quad (6.12.2.2.4d-8)$$

where:

b_f = flange width (in.). For double angles, b_f shall be taken as the full width of a single flange leg.

M_p = plastic moment = $F_y Z_x \leq 1.6 M_y$ (kip-in.)

M_y = yield moment = $F_y S_{xc} \leq M_p$ (kip-in.)

S_{xc} = elastic section modulus about the x-axis with respect to the tee flange or double-angle flange legs subject to compression, as applicable (in.³)

t_f = tee flange thickness or thickness of double-angle flange legs, as applicable (in.)

Z_x = plastic section modulus about the x-axis (in.³)

Flanges of fabricated T-sections in compression or tension shall satisfy Eq. 6.10.2.2-1.

6.12.2.2.4e—Local Buckling of Tee Stems and Double-Angle Web Legs

C6.12.2.2.4e

For tee stems subject to compression, the nominal flexural resistance based on local buckling of the stem shall be taken as:

Separate equations for checking local buckling of tee stems and double-angle web legs subject to compression are provided herein. The equations are taken from AISC (2022b). The derivation of the equations is described in the Commentary to Section F9 of AISC (2022b).

$$M_n = F_{cr} S_x \quad (6.12.2.2.4e-1)$$

in which:

F_{cr} = critical stress (ksi), taken as:

- If $\frac{d}{t_w} \leq 0.84 \sqrt{\frac{E}{F_y}}$, then

$$F_{cr} = F_y \quad (6.12.2.2.4e-2)$$

- If $0.84 \sqrt{\frac{E}{F_y}} < \frac{d}{t_w} \leq 1.52 \sqrt{\frac{E}{F_y}}$, then

consideration of compression flange residual stress effects (in.)

$$= 1.95 r_{ts} \frac{E}{0.7 F_y} \sqrt{\frac{Jc}{S_x h_o}} \sqrt{1 + \sqrt{1 + 6.76 \left(\frac{0.7 F_y}{E} \frac{S_x h_o}{Jc} \right)^2}} \quad (6.12.2.2.5-8)$$

$$r_{ts}^2 = \frac{\sqrt{I_y C_w}}{S_x} \quad (6.12.2.2.5-9)$$

where:

- C_b = moment-gradient modifier, determined as specified in Article A6.3.3.1
- L_b = unbraced length (in.)
- b = distance between the toe of the flange and the centerline of the web (in.)
- h_o = distance between flange centroids (in.)
- I_y = moment of inertia about the y -axis (in.⁴)
- J = St. Venant torsional constant (in.⁴)
- r_{ts} = radius of gyration used in the determination of L_r (in.)
- r_y = radius of gyration about the y -axis (in.)
- S_x = elastic section modulus about the x -axis (in.³)
- t_f = thickness of the flange (in.); for rolled channels, use the average thickness
- t_w = thickness of the web (in.)

For channels in flexure about their weak axis, the nominal flexural resistance shall be determined according to the provisions specified in Article 6.12.2.2.1, with λ_y taken as b_f/t_f , where b_f is the full width of the flange and t_f is the flange thickness taken as the average flange thickness for rolled channels. The nominal flexural resistance shall not exceed $1.6 F_y S_y$, where S_y is the elastic section modulus about the weak axis.

The flange slenderness, λ_{yf} , of fabricated or bent-plate channels shall satisfy:

$$\lambda_f \leq \lambda_{pf} \quad (6.12.2.2.5-10)$$

in which:

- λ_f = flange slenderness of the channel = b_f/t_f
- λ_{pf} = limiting slenderness for a compact flange

$$= 0.38 \sqrt{\frac{E}{F_y}} \quad (6.12.2.2.5-11)$$

where:

- b_f = full width of the flange (in.)
- t_f = flange thickness (in.)

The web slenderness of fabricated or bent-plate channels shall satisfy:

$$\frac{D}{t_w} \leq \lambda_{pw} \quad (6.12.2.2.5-12)$$

in which:

λ_{pw} = limiting slenderness for a compact web

$$= 3.76 \sqrt{\frac{E}{F_y}} \quad (6.12.2.2.5-13)$$

where:

D = web depth (in.)

t_w = web thickness (in.)

6.12.2.2.6—Single Angles

Single angles should not be used as pure flexural members. Single angles subject to combined axial compression and flexure may be designed according to the provisions specified in Article 6.9.4.4.

C6.12.2.2.6

Single angles are not typically intended to serve as pure flexural members in bridge applications. In most practical applications, single angles are subject to flexure about both principal axes due to the eccentricity of applied axial loads. The condition of flexure due to eccentric axial tension is primarily addressed through the use of the shear lag coefficient, U , specified in Article 6.8.2.2. The condition of flexure due to eccentric axial compression may be efficiently handled through the use of an effective slenderness ratio, $(K\ell/r)_{eff}$, as specified in Article 6.9.4.4, which allows single angles satisfying certain specified conditions to be designed as axially loaded compression members for flexural buckling only. Thus, the calculation of the nominal flexural resistance M_n of a single-angle member is typically not required for these common cases. In certain unusual cases discussed in Article C6.9.4.4, single angles subject to combined flexure and axial compression must be evaluated as beam-columns according to the provisions specified in Section H2 of AISC (2022b) in lieu of using the effective slenderness ratio. In such cases, M_n of the single-angle member may be determined according to the procedures given in Section F10 of AISC (2022b).

6.12.2.2.7—Rectangular Bars and Solid Rounds

For rectangular bars and solid rounds in flexure, the nominal flexural resistance shall be taken as the smaller value based on yielding or LTB, as applicable.

For yielding, the nominal flexural resistance shall be taken as:

- For rectangular bars with $\frac{L_b d}{t^2} \leq \frac{0.08 E}{F_y}$ in flexure about their major geometric axis, rectangular bars in flexure about their minor geometric axis, and solid rounds:

$$M_n = M_p = F_y Z \leq 1.6 M_y \quad (6.12.2.2.7-1)$$

where:

C6.12.2.2.7

These provisions apply to solid bars of round or rectangular cross-section and are taken from AISC (2022b). The nominal flexural resistance of these sections will typically be controlled by yielding, except for rectangular bars with a depth larger than the width, which may be controlled by LTB. Since the shape factor for a rectangular cross-section is 1.5 and for a round cross-section is 1.7, the potential for excessive deflections or permanent deformations under service conditions should be considered.

- d = depth of the rectangular bar (in.)
 F_y = specified minimum yield strength (ksi)
 L_b = unbraced length for lateral displacement or twist, as applicable (in.)
 M_p = plastic moment (kip-in.)
 M_y = yield moment (kip-in.)
 t = width of the rectangular bar parallel to the axis of bending (in.)
 Z = plastic section modulus (in.³)

For LTB, the nominal flexural resistance shall be taken as follows for rectangular bars in flexure about their major geometric axis:

- If $\frac{0.08 E}{F_y} < \frac{L_b d}{t^2} \leq \frac{1.9 E}{F_y}$, then:

$$M_n = C_b \left[1.52 - 0.274 \left(\frac{L_b d}{t^2} \right) \frac{F_y}{E} \right] M_y \leq M_p \quad (6.12.2.2.7-2)$$

- If $\frac{L_b d}{t^2} > \frac{1.9 E}{F_y}$, then:

$$M_n = F_{cr} S_x \leq M_p \quad (6.12.2.2.7-3)$$

in which:

$$F_{cr} = \frac{1.9 E C_b}{\frac{L_b d}{t^2}} \text{ (ksi)} \quad (6.12.2.2.7-4)$$

where:

- C_b = moment-gradient modifier, determined as specified in Article A6.3.3.1
 S_x = section modulus about the major geometric axis (in.³)

For rectangular bars in flexure about their minor geometric axis and for solid rounds, LTB shall not be considered.

6.12.2.3—Composite Members

6.12.2.3.1—Concrete-Encased Shapes

C6.12.2.3.1

For concrete-encased shapes that satisfy the provisions of Article 6.9.5.2.3, the nominal resistance of concrete-encased shapes subjected to flexure without compression shall be taken as the lesser of:

$$M_n = M_{ps}, \text{ or} \quad (6.12.2.3.1-1)$$

$$M_n = M_{yc} \quad (6.12.2.3.1-2)$$

The behavior of the concrete-encased shapes and concrete-filled tubes covered in this Article is discussed extensively in Galambos (1998) and AISC (2022b). Such members are most often used as columns or beam columns. The provisions for circular concrete-filled tubes also apply to concrete-filled pipes.

For the purpose of Article 6.9.2.2, the nominal flexural resistance of concrete-encased shapes subjected to compression and flexure shall be taken as:

- If $\frac{P_u}{\phi_c P_n} \geq 0.3$, then:

$$M_n = Z F_y + \frac{(d - 2c) A_r F_{yr}}{3} + \left(\frac{d}{2} - \frac{A_w F_y}{1.7 f'_c b} \right) A_w F_y \quad (6.12.2.3.1-3)$$

- If $0.0 < \left(\frac{P_u}{\phi_c P_n} \right) < 0.3$, then:

M_n shall be determined by a linear interpolation between the M_n value given by Eq. 6.12.2.3.1-1 or 6.12.2.3.1-2 at $P_u = 0$ and the M_n value given by Eq. 6.12.2.3.1-3 at $(P_u/\phi_c P_n) \geq 0.3$

where:

- P_u = axial compressive force due to the factored loading (kip)
- P_n = nominal compressive resistance, specified in Article 6.9.5.1 (kip)
- ϕ_c = resistance factor for axial compression, specified in Article 6.5.4.2
- M_{ps} = plastic moment of the steel section (kip-in.)
- M_{yc} = yield moment of the composite section, determined as specified in Article D6.2 (kip-in.)
- Z = plastic section modulus of the steel section about the axis of bending (in.³)
- A_w = web area of the steel section (in.²)
- f'_c = specified minimum 28-day compressive strength of the concrete (ksi)
- A_r = area of the longitudinal reinforcement (in.²)
- c = distance from the center of the longitudinal reinforcement to the nearest face of the member in the plane of bending (in.)
- d = depth of the member in the plane of flexure (in.)
- b = width of the member perpendicular to the plane of flexure (in.)
- F_{yr} = specified minimum yield strength of the longitudinal reinforcement (ksi)

6.12.2.3.2—Concrete-Filled Tubes

The nominal flexural resistance of concrete-filled tubes that satisfy the limitations in Articles 6.9.5.2 may be taken as:

- If $\frac{D}{t} < 2.0 \sqrt{\frac{E}{F_y}}$, then:

$$M_n = M_{ps} \quad (6.12.2.3.2-1)$$

The equation for M_n when $(P_u/\phi_c P_n) \geq 0.3$ is an approximate equation for the plastic moment resistance that combines the flexural strengths of the steel shape, the reinforcing bars, and the reinforced concrete. These resistances are defined in the first, second, and third terms of the equation respectively (Galambos, 1998). The equation has been verified by extensive tests (Galambos and Chapuis, 1980).

No test data are available on the loss of bond in composite beam columns. However, consideration of tensile cracking of concrete suggests $(P_u/\phi_c P_n) = 0.3$ as a conservative limit (AISC, 1999). It is assumed that when $(P_u/\phi_c P_n)$ is less than 0.3, the nominal flexural resistance is reduced below the plastic moment resistance of the composite section given by Eq. 6.12.2.3.1-3.

When there is no axial load, even with full encasement, it is assumed that the bond is only capable of developing the lesser of the plastic moment resistance of the steel section or the yield moment resistance of the composite section.

C6.12.2.3.2

Eqs. 6.12.2.3.2-1 and 6.12.2.3.2-2 represent a step function for nominal flexural resistance. No accepted transition equation is available at this writing.

- If $2.0\sqrt{\frac{E}{F_y}} < \frac{D}{t} \leq 8.8\sqrt{\frac{E}{F_y}}$, then:

$$M_n = M_{yc} \quad (6.12.2.3.2-2)$$

6.12.2.3.3—CFSTs

The material-based nominal P-M interaction curve of circular CFSTs that satisfy the limitations in Article 6.9.6.2 shall be computed using one of the following methods:

- the plastic stress distribution method (PSDM), or
- the strain compatibility method (SCM).

The crack control provisions of Article 5.8.2.6 and the temperature and shrinkage reinforcement requirements of Article 5.10.6 shall not apply to CFSTs.

C6.12.2.3.3

The PSDM and SCM methods are permitted for evaluating the resistance of CFST members without consideration of buckling. The resistances obtained in experiments performed by a wide range of researchers on CFST members have been compared to the resistances predicted by the PSDM and SCM methods. Both methods provided conservative estimates of the resistance of CFST members. The comparisons were based upon the measured bending moment with a given applied axial load. The experiments showed that the CFST members developed 24 percent larger bending moment than predicted by the PSDM and 65 percent larger bending moment than predicted by the SCM. The standard deviation of the measured bending moment was 18 percent of the mean bending moment for the PSDM method and 114 percent of the mean bending moment for the SCM method. While the SCM has considerably more scatter in its predicted resistance, it provides estimates of curvature and nonlinear deformation; the PSDM does not provide any information on strain or deformation (Marson and Bruneau, 2004) (Roeder, Lehman, and Bishop, 2010). Research by Kenarangi and Bruneau (2017) has validated the PSDM method for various D/t ratios out to large displacements.

The PSDM is recognized in AISC (2022b). The method is illustrated in Figure C6.12.2.3.3-1. The method uses the full yield strength of the steel in tension and compression. Even under higher axial stresses, the full yield strength of the steel can be achieved because the concrete fill restrains local buckling of the steel. The compressive capacity of the concrete is approximated using a uniform concrete stress distribution with a magnitude of stress equal to $0.95f'_c$ over the entire compressive region. The coefficient of 0.95 on the concrete compressive strength is higher than the typical coefficient of 0.85 used for reinforced concrete flexural strength calculations in recognition of the increased confinement of the concrete and the resulting increased deformation capacity provided by the circular steel tube; comparison with test results indicate this method provides an accurate prediction of the flexural resistance. The axial load, P , and bending moment, M , are in equilibrium with the stress state and this neutral axis depth, with the resulting P and M values defining one point on the P-M interaction curve. Other points are defined for other neutral axis locations to fully establish the complete PSDM material-based P-M interaction curve.

Figure C6.12.2.3.3-1—PSDM Model

For combined axial load and flexure, the PSDM is defined by using multiple assumed locations of the neutral axis to obtain a material-based P-M interaction curve, as illustrated in Figure C6.12.2.3.3-2. This interaction curve defines the material-based resistance of composite CFSTs that is not affected by buckling, secondary moments or P- δ effects.

Figure C6.12.2.3.3-2—Material-based P-M Interaction Curves

While the PSDM is recognized in other design specifications, closed-form solutions of the complete material-based interaction curves are provided as follows for circular CFSTs with no internal reinforcement or with one radial row of internal reinforcement.

$$\begin{aligned}
 P_n = & F_{yt} t r_m \left[(\pi - 2\theta_s) - (\pi + 2\theta_b) \right] \\
 & + t_b r_b \left[F_{yb} (\pi - 2\theta_b) - (F_{yb} - 0.95 f'_c) (\pi + 2\theta_b) \right] \\
 & + \frac{0.95 f'_c}{2} \left[(\pi - 2\theta_s) r_i^2 - 2yc \right]
 \end{aligned}
 \tag{C6.12.2.3.3-1}$$

$$M_n = 0.95 f'_c c \left[(r_i^2 - y^2) - \frac{c^2}{3} \right] + 4 F_{yst} t c \frac{r_m^2}{r_i} + 4 F_{yb} t_b c_b r_b$$

(C6.12.2.3.3-2)

in which:

$$r_m = r - \frac{t}{2}$$

(C6.12.2.3.3-3)

$$\theta_s = \sin^{-1} \left(\frac{y}{r_m} \right)$$

(C6.12.2.3.3-4)

$$\theta_b = \sin^{-1} \left(\frac{y}{r_b} \right)$$

(C6.12.2.3.3-5)

$$c = r_i \cos \theta_s$$

(C6.12.2.3.3-6)

$$c_b = r_b \cos \theta_b$$

(C6.12.2.3.3-7)

$$t_b = \frac{n A_b}{2 \pi r_b}$$

(C6.12.2.3.3-8)

where:

- A_b = area of a single reinforcing bar (in.²)
- c = one-half the chord length for a given stress state, as shown in Figure C6.12.2.3.3-1 (in.)
- c_b = one-half the chord length for a given stress state of a fictional tube modeling the internal reinforcement (in.)
- F_{yb} = specified minimum yield strength of the steel bars used for internal reinforcement (ksi)
- F_{yst} = specified minimum yield strength of the steel tube (ksi)
- f'_c = specified minimum 28-day compressive strength of the concrete (ksi)
- M_n = nominal flexural resistance as a function of the nominal axial resistance, P_n (kip-in.)
- n = number of uniformly spaced internal reinforcing bars, as shown in Figure C6.12.2.3.3-1
- P_n = nominal compressive resistance of the member as function of the nominal flexural resistance, M_n (kips)
- r = radius to the outside of the steel tube, as shown in Figure C6.12.2.3.3-1 (in.)
- r_b = radius to the center of the internal reinforcing bars, as shown in Figure C6.12.2.3.3-1 (in.)
- r_i = radius to the inside of the steel tube, as shown in Figure C6.12.2.3.3-1 (in.)
- r_m = radius to the center of the steel tube, as shown in Figure C6.12.2.3.3-1 (in.)
- t = thickness of steel tube, as shown in Figure C6.12.2.3.3-1 (in.)

- t_b = thickness of a fictional steel tube used to model the contribution of the internal reinforcement, as shown in Figure C6.12.2.3.3-1 (in.)
 y = distance from the center of the tube to neutral axis for a given stress state, as shown in Figure C6.12.2.3.3-1 (in.)
 θ_b = angle used to define the length c_b for a given stress state (radians)
 θ_s = angle used to define the length c for a given stress state (radians)

Smaller D/t values result in larger resistance because the area of steel is larger than a tube with the same diameter and smaller thickness. Larger D/t ratios result in significantly increased normalized flexural resistances for modest compressive loads relative to the flexural resistance corresponding to zero axial load because of the increased contribution of the concrete fill.

In the expressions, a positive value of P implies a compressive force, and y and θ are positive according to the sign convention shown in Figure C6.12.2.3.3-1. The material-based P-M interaction curve is generated by solving the equations for discrete values of y , and connecting those points where y varies between plus and minus r_b . For the case in which internal reinforcement is not present or is not considered, the variables A_b and t_b are equal to zero and several terms do not contribute to the resistance. For the case in which internal reinforcement is considered, θ_b shall be taken as positive $\pi/2$ if the ratio y/r_b is greater than one; θ_b shall be taken as negative $\pi/2$ if y/r_b is less than one. The composite plastic moment resistance without axial load, M_o , corresponds to the point on the material-based P-M interaction curve where P_n from Eq. C6.12.2.3.3-1 equals zero, which can be determined through linear interpolation.

For the cases where a column is integral with a CFST, moment transfer can be either by transferring tension between the reinforcing of the column that extends into the top of the CFST, and the reinforcing inside the CFST, or if the CFST is unreinforced, through the shear head behavior identified by Kenarangi and Bruneau (2017).

6.12.3—Nominal Shear Resistance of Composite Members

6.12.3.1—Concrete-Encased Shapes

The nominal shear resistance may be taken as:

$$V_n = 0.58F_{yw}Dt_w + \frac{F_{yv}A_v(d-c)}{s} \quad (6.12.3.1-1)$$

where:

F_{yw} = specified minimum yield strength of the web of the steel shape (ksi)

- F_{yr} = specified minimum yield strength of the transverse reinforcement (ksi)
 D = web depth of the steel shape (in.)
 t_w = thickness of the web or webs of the steel shape (in.)
 A_v = cross-sectional area of transverse reinforcement bars that intercept a diagonal shear crack (in.²)
 s = longitudinal spacing of transverse reinforcement (in.)
 d = depth of the member in the plane of shear (in.)
 c = distance from the center of the longitudinal reinforcement to the nearest face of the member in the plane of bending (in.)

6.12.3.2—Concrete-Filled Tubes

6.12.3.2.1—Rectangular Tubes

The nominal shear resistance may be taken as:

$$V_n = 1.16 D t_w F_y \quad (6.12.3.2.1-1)$$

where:

- D = web depth of the tube (in.)
 t_w = wall thickness of the tube (in.)

6.12.3.2.2—CFSTs

C6.12.3.2.2

The nominal shear resistance of composite CFSTs, both with and without internal reinforcement, shall be taken as:

$$V_n = V_s + V_c \quad (6.12.3.2.2-1)$$

in which:

$$V_s = \frac{2 D t}{\sqrt{3}} F_y \quad (6.12.3.2.2-2)$$

$$V_c = 0.0316 \beta \sqrt{f'_c} A_c \quad (6.12.3.2.2-3)$$

$$\beta = 6.0 \quad (6.12.3.2.2-4)$$

where:

- V_s = nominal shear resistance provided by the steel tube (kips)
 V_c = nominal shear resistance provided by the concrete infill (kips)
 D = outer diameter of the steel tube (in.)
 t = wall thickness of the steel tube (in.)
 F_y = specified minimum yield strength of the steel tube (ksi)
 f'_c = compressive strength of the concrete fill (ksi)
 A_c = area of the concrete fill (in.²)

Previous editions of these Specifications limited the shear resistance of composite circular steel tubes to that of the steel tube alone. Research by Roeder et al. (2016) and Kenarangi and Bruneau (2017) indicate the concrete fill adds substantially to the resistance. For very short shear spans, approaching the diameter of the steel tube, the shear behavior is governed by the formation of a strut in the infill concrete.

6.13—CONNECTIONS AND SPLICES

6.13.1—General

Except as specified herein, connections and splices for primary members subject only to axial tension or compression shall be designed at the strength limit state for not less than the larger of:

- the average of the factored axial force effect at the point of splice or connection and the factored axial resistance of the member or element at the same point, or
- 75 percent of the factored axial resistance of the member or element.

Connections and splices for primary members subjected to combined force effects, other than splices for flexural members, shall be designed at the strength limit state for the larger of:

- the calculated combined factored force effects, or
- 75 percent of the factored axial resistance of the member determined as specified in Articles 6.8.2 or 6.9.2, as applicable.

Bolted splices for flexural members shall be designed at the strength limit state as specified in Article 6.13.6.1.3. Welded splices for flexural members shall be designed at the strength limit state as specified in Article 6.13.6.2.

Where diaphragms, cross-frames, lateral bracing, stringers, or floorbeams for straight or horizontally curved flexural members are included in the structural model used to determine force effects, or alternatively, are designed for explicitly calculated force effects from the results of a separate investigation, end connections for these bracing members shall be designed for the calculated factored member force effects. Otherwise, the end connections for these members shall be designed according to the 75 percent resistance provision contained herein.

Unless otherwise permitted by the contract documents, standard-size bolt holes shall be used in connections in horizontally curved bridges.

Insofar as practicable, connections should be made symmetrical about the axis of the members. Connections, except for lacing bars and handrails, shall contain not less than two bolts. Members, including bracing, should be connected so that their gravity axes will intersect at a point. Eccentric connections should be avoided. Where eccentric connections cannot be avoided, members and connections shall be proportioned for the combined effects of shear and moment due to the eccentricity.

In the case of connections that transfer total member end shear, the gross section shall be taken as the gross section of the connected elements.

C6.13.1

For primary members subjected to force effects acting in multiple directions due to combined loading, such as members in rigid frames, arches, and trusses, a clarification of the design requirements is provided herein related to the determination of the factored resistance of the member. Connections and splices for such members are to be designed for the larger of the calculated combined factored force effects, preferably determined using concurrent forces or conservatively determined using envelope forces if only such forces are available, or 75 percent of the factored axial resistance of the member. The 75 percent resistance requirement is retained to provide a minimum level of stiffness and to be consistent with past practice for the design of connections and splices for axially loaded members.

The exception for bracing members in straight or horizontally curved girder bridges that are included in the structural model using to determine force effects is a result of previous experience with end connection details for these members that were developed invoking the 75 percent and average load provisions specified herein. These details tended to become so large as to be unwieldy resulting in large eccentricities and force concentrations. It has been decided that the negatives associated with these connections justified the exception permitted herein.

Standard-size bolt holes in connections in horizontally curved bridges ensure that the steel fits together in the field.

The configuration of some welded end connections, such as the connection of a cross-frame member to a gusset plate, may result in an unbalanced weld condition where the centroid of the weld group is offset from the centroid of the member, producing an eccentricity in the plane of the connection. In the case of single angles, the member itself is unsymmetrical and an eccentricity is created unless the weld group is balanced to align with the member centroid. Detailing excessively oversized or odd-shaped gusset plates solely to allow for the unequal length longitudinal welds necessary to achieve a balanced weld configuration in this case is generally impractical and is discouraged. Instead, consider evaluating the

The thickness of end connection angles of stringers, floorbeams and girders shall not be less than 0.375 in. End connections for stringers, floorbeams and girders should be made with two angles. Bracket or shelf angles that may be used to furnish support during erection shall not be considered in determining the number of fasteners required to transmit end shear.

End connections of stringers, floorbeams, and girders should be bolted with high-strength bolts. Welded connections may be permitted when bolting is not practical. Where used, welded end connections shall be designed for vertical loads and the bending moment resulting from the restraint against end rotation.

Where timber stringers frame into steel floorbeams, shelf angles with stiffeners shall be provided to support the total reaction. Shelf angles shall not be less than 0.4375 in. thick.

6.13.2—Bolted Connections

6.13.2.1—General

Bolted steel parts may be coated or uncoated, and shall fit solidly together after the bolts are tightened. The contract documents shall specify that all joint surfaces, including surfaces adjacent to the bolt head and nut, shall be specified to be free of scale, except tight mill scale, and free of dirt or other foreign material.

High-strength bolted joints shall be designated as either slip-critical or bearing-type connections. For slip-critical connections, the friction value shall be consistent with the specified condition of the faying surfaces as specified in Article 6.13.2.8. All material within the grip of the bolt shall be steel.

6.13.2.1.1—Slip-Critical Connections

Pretensioned high-strength bolted joints located where stress and strain due to joint slippage would be detrimental to the serviceability of the structure or may adversely affect the geometry of the structure shall be designated in the contract documents as slip-critical connections. Except as specified herein, slip-critical connections shall include:

- Bolted field splices in flexural members;
- Joints in shear with bolts installed in oversized holes;
- Joints in shear with bolts installed in short- and long-slotted holes where the force on the joint is in a direction other than perpendicular to the axis of the slot, except where the engineer intends otherwise and so indicates in the contract documents;

connection as an eccentrically loaded weld group, which causes additional shear loading of the welds (Salmon et al., 2009).

These provisions apply to end connection angles used to connect stringers to floorbeams, floorbeams to girders, or both.

C6.13.2.1.1

In bolted slip-critical connections subject to shear, the load is transferred between the connected parts by friction up to a certain level of force that is dependent upon the total clamping force on the faying surfaces and the coefficient of friction of the faying surfaces. The connectors are not subject to shear nor is the connected material subject to bearing stress. Slip occurs as loading is increased to a level in excess of the frictional resistance between the faying surfaces, but failure in the sense of rupture does not occur. As a result, slip-critical connections are able to resist even greater loads by shear and bearing against the connected material. The strength of the connection is not related to the slip load. These Specifications require that the slip resistance and the shear and bearing resistance be computed separately. Because the combined effect of frictional resistance with shear or bearing has not been systematically studied and

- Joints in which welds and bolts share in transmitting load at a common faying surface;
- Joints in axial tension or combined axial tension and shear;
- Joints in axial compression only, with standard or slotted holes in only one ply of the connection with the direction of the load perpendicular to the direction of the slot, except for connections designed according to the provisions specified in Article 6.13.6.1.2; and
- Joints in which, in the judgment of the Engineer, any slip would be critical to the performance of the joint or the structure and which are so designated in the contract documents.

Joints of diaphragm, cross-frame, and lateral bracing members in beam or girder bridges with pretensioned high-strength bolts installed in standard holes should be designed only as bearing-type connections as specified in Article 6.13.2.1.2.

Pretensioned high-strength bolted connections in beam or girder bridges that are designed as slip-critical connections shall be proportioned to prevent slip under the factored loads during the deck placement as specified in Article 6.10.3.1. Such connections, except for connections of lateral bracing members, shall also be proportioned to prevent slip under Load Combination Service II, as specified in Table 3.4.1-1, and to provide bearing, shear, and tensile resistance at the applicable strength limit state load combinations assuming the connection has slipped and gone into bearing against the connected material. The provisions of Article 6.13.2.2 shall apply.

is uncertain, any potential greater resistance due to combined effect is ignored.

For slotted holes, perpendicular to the slot is defined as an angle between approximately 80 to 100 degrees to the axis of the slot.

Joints of diaphragm, cross-frame, and lateral bracing members in beam or girder bridges with pretensioned high-strength bolts installed in standard holes do not need to be designed as slip-critical connections as field experience has indicated that slip is not likely and that any slip that may occur in these connections is not anticipated to be detrimental to the geometry or serviceability of the structure.

Top-flange lateral bracing members in tub girders are typically shop-installed with standard holes provided in the connections, and therefore need not be designed as slip-critical connections unless specified otherwise by the Owner. Field-installed lateral bracing members in beam or girder bridges with oversize holes provided in the connection of the bracing member to the lateral connection plate or to the flange, as applicable, to aid in fit-up are to be designed as slip-critical connections under the factored loads during the deck placement.

Faying surfaces of joints that are designed as bearing-type connections need not satisfy the surface condition preparation specified in Article 6.13.2.8 for slip-critical connections; coatings are permitted in bearing-type connections.

To control deformations during the deck placement caused by slip in the joints that could adversely affect the geometry of the structure, pretensioned high-strength bolted connections in beam or girder bridges that are designed as slip-critical connections, i.e., diaphragm, cross-frame or lateral bracing members that are provided with oversize or slotted holes in the connections and bolted field splices, are to be proportioned to prevent slip under the factored loads during the deck placement. Wind load for the active work zone condition during the deck placement as defined in the *AASHTO Guide Specifications for Wind Loads on Bridges During Construction* should also be considered in proportioning such connections in diaphragm, cross-frame, and lateral bracing members.

To control permanent deformations under overloads caused by slip in joints that could adversely affect the serviceability of the structure, pretensioned high-strength bolted connections in beam or girder bridges that are designed as slip-critical connections, except for connections of lateral bracing members, are also to be proportioned to prevent slip under Load Combination Service II. This provision need not be applied to slip-critical connections in lateral bracing members as the consequence of any slip in the connections of these members is not likely to be detrimental to the serviceability of the structure under this load condition. This provision is intended to apply to the design live load specified in Article 3.6.1.1. If this provision were to be applied to a situation involving Owner-specified special

design vehicles and/or evaluation permit vehicles, a reduction in the load factor for live load should be considered. The connections affected by this provision must also be checked for the applicable strength load combinations specified in Table 3.4.1-1, assuming the connection has slipped at these high loads and gone into bearing against the connected material.

6.13.2.1.2—Bearing-Type Connections

Bearing-type connections shall be permitted only for joints subjected to axial compression or for joints of diaphragm, cross-frame, or lateral bracing members in beam or girder bridges with high-strength bolts installed in standard holes. The factored resistance, R_r , of bearing-type connections shall be determined as specified in Article 6.13.2.2 for bolted connections at the strength limit state. High-strength bolted bearing-type connections shall be fully pretensioned.

Where permissible, connections using ASTM A307 bolts or nonpretensioned high-strength bolts shall be designed as bearing-type connections.

6.13.2.2—Factored Resistance

For slip-critical connections, the factored resistance, R_r , of a bolt at the Service II Load Combination shall be taken as:

$$R_r = R_n \quad (6.13.2.2-1)$$

where:

R_n = nominal resistance as specified in Article 6.13.2.8

The factored resistance, R_r or T_r , of a bolted connection at the strength limit state shall be taken as either:

$$R_r = \phi R_n \quad (6.13.2.2-2)$$

$$T_r = \phi T_n \quad (6.13.2.2-3)$$

where:

R_n = nominal resistance of the bolt, connection, or connected material as follows:

- For bolts in shear, R_n shall be taken as specified in Article 6.13.2.7.
- For the connected material in bearing joints, R_n shall be taken as specified in Article 6.13.2.9.
- For connected material in tension or shear, R_n shall be taken as specified in Article 6.13.5.

C6.13.2.1.2

In bolted bearing-type connections, the load is resisted by shear in the fastener and bearing upon the connected material, plus some uncertain amount of friction between the faying surfaces. The final failure will be by shear failure of the connectors, by tear-out of the connected material, or by unacceptable ovalization of the holes. Final failure load is independent of the clamping force provided by the bolts (Kulak et al., 1987).

C6.13.2.2

Eq. 6.13.2.2-1 applies to a service limit state for which the resistance factor is 1.0, and, hence, is not shown in the equation.

- T_n = nominal resistance of a bolt as follows:
- For bolts in axial tension, T_n shall be taken as specified in Article 6.13.2.10.
 - For bolts in combined axial tension and shear, T_n shall be taken as specified in Article 6.13.2.11.
- ϕ = resistance factor for bolts specified in Article 6.5.4.2, taken as:
- ϕ_s for bolts in shear,
 - ϕ_t for bolts in tension,
 - ϕ_{bb} for bolts bearing on material,
 - ϕ_v or ϕ_u for connected material in tension, as appropriate, or
 - ϕ_v or ϕ_{vu} for connected material in shear.

6.13.2.3—Bolts, Nuts, and Washers

6.13.2.3.1—Bolts and Nuts

The provisions of Article 6.4.3 shall apply.

6.13.2.3.2—Washers

Hardened washers shall be required for connections using high-strength bolts as specified in Article 17.7.4.1 of the *AASHTO LRFD Steel Bridge Fabrication Specifications*. Hardened washers shall satisfy the requirements specified in Article 6.4.3.1.3.

Direct tension indicators shall not be installed over oversize or slotted holes in an outer ply, unless a hardened washer or a structural plate washer is also provided.

6.13.2.4—Holes

6.13.2.4.1—Type

6.13.2.4.1a—General

Unless specified otherwise, standard holes shall be used in high-strength bolted connections.

6.13.2.4.1b—Oversize Holes

Oversize holes may be used in any or all plies of slip-critical connections. They shall not be used in bearing-type connections.

6.13.2.4.1c—Short-Slotted Holes

Short-slotted holes may be used in any or all plies of slip-critical or bearing-type connections. The slots may be used without regard to direction of loading in slip-critical connections, but the length shall be normal to the direction of the load in bearing-type connections.

6.13.2.4.1d—Long-Slotted Holes

Long-slotted holes may be used in only one ply of either a slip-critical or bearing-type connection. Long-

slotted holes may be used without regard to direction of loading in slip-critical connections but shall be normal to the direction of load in bearing-type connections.

6.13.2.4.2—Size

The dimension of the holes shall not exceed the values given in Table 6.13.2.4.2-1.

Table 6.13.2.4.2-1—Maximum Hole Sizes

Bolt Dia. d in.	Standard Dia. in.	Oversize Dia. in.	Short Slot Width $\times$ Length in.	Long Slot Width $\times$ Length in.
$\frac{5}{8}$	$\frac{11}{16}$	$\frac{13}{16}$	$\frac{11}{16} \times \frac{7}{8}$	$\frac{11}{16} \times 1\frac{9}{16}$
$\frac{3}{4}$	$\frac{13}{16}$	$\frac{15}{16}$	$\frac{13}{16} \times 1$	$\frac{13}{16} \times 1\frac{7}{8}$
$\frac{7}{8}$	$\frac{15}{16}$	$1\frac{1}{16}$	$\frac{15}{16} \times 1\frac{1}{8}$	$\frac{15}{16} \times 2\frac{3}{16}$
1	$1\frac{1}{8}$	$1\frac{1}{4}$	$1\frac{1}{8} \times 1\frac{5}{16}$	$1\frac{1}{8} \times 2\frac{1}{2}$
$\geq 1\frac{1}{8}$	$d + \frac{1}{8}$	$d + \frac{5}{16}$	$d + \frac{1}{8} \times d + \frac{3}{8}$	$d + \frac{1}{8} \times 2.5d$

6.13.2.5—Size of Bolts

Bolts shall not be less than 0.625 in. in diameter. Bolts 0.625 in. in diameter shall not be used in primary members, except in 2.5-in. legs of angles and in flanges of sections whose dimensions require 0.625-in. fasteners to satisfy other detailing provisions herein. Use of structural shapes that do not allow the use of 0.625-in. fasteners shall be limited to handrails.

6.13.2.6—Spacing of Bolts

6.13.2.6.1—Minimum Spacing and Clear Distance

The minimum spacing between centers of bolts in standard holes shall be no less than three times the diameter of the bolt. When oversize or slotted holes are used, the minimum clear distance between the edges of adjacent bolt holes in the direction of the force and transverse to the direction of the force shall not be less than twice the diameter of the bolt.

C6.13.2.6.1

In uncoated weathering steel structures, pack-out is not expected to occur in joints where bolts satisfy the maximum spacing requirements specified in Article 6.13.2.6.2 (Brockenbrough, 1983).

6.13.2.6.2—Maximum Spacing for Sealing Bolts

For sealing against the penetration of moisture in joints, the spacing on a single line adjacent to a free edge of an outside plate or shape shall satisfy:

$$s \leq (4.0 + 4.0t) \leq 7.0 \quad (6.13.2.6.2-1)$$

If there is a second line of fasteners uniformly staggered with those in the line adjacent to the free edge, at a gauge less than $1.5 + 4.0t$, the staggered spacing, s , in two such lines, considered together, shall satisfy:

$$s \leq 4.0 + 4.0t - \left(\frac{3.0g}{4.0} \right) \leq 7.0 \quad (6.13.2.6.2-2)$$

The staggered spacing need not be less than one-half the requirement for a single line.

where:

- t = thickness of the thinner outside plate or shape (in.)
 g = gauge between bolts (in.)

6.13.2.6.3—Maximum Pitch for Stitch Bolts

Stitch bolts shall be used in mechanically fastened built-up members where two or more plates or shapes are in contact.

The pitch of stitch bolts in compression members shall not exceed $12.0t$. The gauge, g , between adjacent lines of bolts shall not exceed $24.0t$. The staggered pitch between two adjacent lines of staggered holes shall satisfy:

$$p \leq 15.0t - \left(\frac{3.0g}{8.0} \right) \leq 12.0t \quad (6.13.2.6.3-1)$$

The pitch for tension members shall not exceed twice that specified herein for compression members. The gauge for tension members shall not exceed $24.0t$. The maximum pitch of fasteners in mechanically fastened built-up members shall not exceed the lesser of the requirements for sealing or stitch.

6.13.2.6.4—Maximum Pitch for Stitch Bolts at the End of Compression Members

The pitch of bolts connecting the component parts of a compression member shall not exceed four times the diameter of the fastener for a length equal to 1.5 times the maximum width of the member. Beyond this length, the pitch may be increased gradually over a length equal to 1.5 times the maximum width of the member until the maximum pitch specified in Article 6.13.2.6.3 is reached.

6.13.2.6.5—End Distance

The end distance for all types of holes measured from the center of the bolt shall not be less than the edge distances specified in Table 6.13.2.6.6-1. When oversize or slotted holes are used, the minimum clear end distance shall not be less than the bolt diameter.

C6.13.2.6.3

The intent of this provision is to ensure that the parts act as a unit and, in compression members, prevent buckling.

C6.13.2.6.5

The minimum edge and end distance requirements specified in Table 6.13.2.6.6-1 are based on standard fabrication practices and workmanship tolerances, and are equivalent to the requirements specified in AISC (2022b). The provisions of Article 6.13.2.9 related to the bearing resistance of bolt holes must be satisfied for all bolt holes, and are used to ensure that sufficient end distances are provided such that bearing and tear-out limits are not exceeded for holes adjacent to all types of edges. It is recommended that edge and end distances larger than these specified minimum edge distances, but not exceeding the maximum edge and end distances specified herein, be permitted to help ensure that the specified minimum distances are not violated during fabrication after allowing for unavoidable workmanship tolerances.

The maximum end distance shall be the maximum edge distance as specified in Article 6.13.2.6.6.

6.13.2.6.6—Edge Distances

The minimum edge distance shall be as specified in Table 6.13.2.6.6-1.

The maximum edge distance shall not be more than eight times the thickness of the thinnest outside plate or 5.0 in.

Table 6.13.2.6.6-1—Minimum Edge Distances

Bolt Diameter, d (in.)	Minimum Edge Distance (in.)
$\frac{5}{8}$	$\frac{7}{8}$
$\frac{3}{4}$	1
$\frac{7}{8}$	$1\frac{1}{8}$
1	$1\frac{1}{4}$
$1\frac{1}{8}$	$1\frac{1}{2}$
$1\frac{1}{4}$	$1\frac{5}{8}$
Over $1\frac{1}{4}$	$1\frac{1}{4} \times d$

6.13.2.7—Shear Resistance

The nominal shear resistance of a high-strength bolt (ASTM F3125/F3125M or ASTM F3148) or an ASTM A307 bolt (Grade A or B) at the strength limit state in joints whose length between extreme fasteners measured parallel to the line of action of the force is less than or equal to 38.0 in. shall be taken as:

- Where threads are excluded from the shear plane:

$$R_n = 0.56 A_b F_{ub} N_s \quad (6.13.2.7-1)$$

- Where threads are included in the shear plane:

$$R_n = 0.45 A_b F_{ub} N_s \quad (6.13.2.7-2)$$

where:

- A_b = area of the bolt corresponding to the nominal diameter (in.²)
- F_{ub} = specified minimum tensile strength of the bolt specified in Article 6.4.3.1.1 (ksi)
- N_s = number of shear planes per bolt

The nominal shear resistance of a bolt in lap splice tension and compression connections greater than 38.0 in. in length shall be taken as 0.83 times the value given by Eq. 6.13.2.7-1 or 6.13.2.7-2.

Shear planes located in the transition length of high-strength bolts should be considered shear planes with the

C6.13.2.7

The nominal resistance in shear is based upon the observation that the shear strength of a single high-strength bolt is about 0.625 times the tensile strength of that bolt (AISC, 2022b). However, in lap splice tension and compression connections with more than two bolts in the line of force, deformation of the connected material causes nonuniform bolt shear force distribution so that the strength of the connection in terms of the average bolt strength decreases as the joint length increases. Rather than provide a function that reflects this decrease in average fastener strength with joint length, a single reduction factor of 0.90 was applied to the 0.625 multiplier. This accommodates bolts in joints up to 38.0 in. in length without seriously affecting the economy of very short joints (Tide, 2010). For connections longer than 38.0 in., an overall reduction factor of 0.75 was found to be appropriate. Therefore, the nominal shear resistance of bolts in joints longer than 38.0 in. must be further reduced by an additional factor of 0.83 or 0.75/0.90. For flange splices, the 38.0-in. length is to be measured between the extreme bolts on only one side of the connection. The potential application of the additional joint length reduction factor of 0.83 applies only to lap splice tension and compression connections and not to web shear-type connections, e.g., web splices. The reduction factor of 0.90 is retained for web shear-type connections since the distribution of the bolt forces is not necessarily uniform. However, a further reduction in the shear resistance based on the joint length is not necessary (RCSC, 2020).

threads included. If the threads of a bolt are included in the shear plane in the joint, the shear resistance of the bolt in all shear planes of the joint shall be the value for threads included in the shear plane.

For ASTM A307 bolts, shear design shall be based on Eq. 6.13.2.7-2. When the grip length of an ASTM A307 bolt exceeds 5.0 diameters, the nominal resistance shall be lowered one percent for each $1/16$ in. of grip in excess of 5.0 diameters.

The average value of the nominal resistance for bolts with threads in the shear plane has been determined by a series of tests to be $0.833 (0.6F_{ub})$, with a standard deviation of 0.03 (Yura et al., 1987). A value of about 0.80 was selected for the specification formula based upon the area corresponding to the nominal body area of the bolt.

Shear planes located in the transition length of high-strength bolts have traditionally been treated as if the threads were excluded from the shear plane. Further evaluation of the transition area and the variations permitted in the manufacturing of bolts in ASME B18.2.6 (2019) (Swanson et al.; 2020a, 2020b) have caused a more conservative approach to be taken in the RCSC Specification (2020), such that shear planes located in the transition length of high-strength bolts should now be considered shear planes with the threads included. The following guidance is provided for determining whether threads are excluded from or included in the shear plane considering the bolt transition length. Unless the use and position of washers and DTIs is clearly identified in the contract documents, consider evaluating conditions with and without one washer and one DTI positioned under the bolt head adjacent to the thicker outer ply. Refer to ASTM F436/F436M for washer thicknesses; the nominal thickness of the typical standard washer is $5/32$ in. Refer to ASME B18.2.6 (2019) or manufacturer data for the appropriate DTI dimensions. If DTIs will not be used, they need not be considered. Sum the grip length of the connection, i.e., the total nominal thicknesses of the connection plies, L_{PLY} in Figure C6.13.2.7-1, the thicknesses of the assumed washer, T , in Figure C6.13.2.7-1, and DTI, F , in Figure C6.13.2.7-1, if considered, plus an additional value specified in Table C-2.2 of RCSC (2020) to allow for manufacturing tolerances and sufficient thread engagement with a heavy hex nut. Round up the sum to the next 0.25-in. increment up to a bolt length of 6.0 in. and to the next 0.5-in. increment for longer bolts (RCSC, 2020) to determine the minimum nominal bolt length, L_{NOM} in Figure C6.13.2.7-1. Next, determine the minimum bolt body length, i.e., the distance from the head of the bolt to the beginning of the transition length, L_B in Figure C6.13.2.7-1, and compare that length to the location of the furthest shear plane measured from the bolt head, L_{SP} in Figure C6.13.2.7-1, to determine whether the threads are excluded or included. The minimum bolt body length can either be determined directly from Table 2.1.9.2-1 of ASME B18.2.6 (2019) using the calculated minimum nominal bolt length and the nominal bolt diameter, or calculated indirectly by subtracting the appropriate thread length, L_T , and transition thread length, Y , found in Table C-2.1 of RCSC (2020) from the calculated minimum nominal bolt length.

Figure C6.13.2.7-1—Dimensions for Determination of Threads Excluded from or Included in the Shear Plane

Short high-strength bolts with lengths indicated in Table 2.5 of RCSC (2020) are fully threaded in accordance with ASME B18.2.6 (2019) and thus should be designed for threads included in the shear plane.

The shear strength of bolts is not affected by pretension in the fasteners, provided that the connected material is in contact at the faying surfaces.

The factored resistance equals the nominal shear resistance multiplied by a resistance factor less than that used to determine the factored resistance of a component. This ensures that the maximum strength of the bridge is limited by the strength of the main members rather than by the connections.

The absence of design strength provisions specifically for the case where a bolt in double shear has a nonthreaded shank in one shear plane and a threaded section in the other shear plane is because of the uncertainty of manner of sharing the load between the two shear areas. It also recognizes that knowledge about the bolt placement, which might leave both shear planes in the threaded section, is not ordinarily available to the designer.

The threaded length of an ASTM A307 bolt is not as predictable as that of a high-strength bolt. The requirement to use Eq. 6.13.2.7-2 reflects that uncertainty.

ASTM A307 bolts with a long grip tend to bend, thus reducing their resistance.

6.13.2.8—Slip Resistance

The nominal slip resistance of a bolt in a slip-critical connection shall be taken as:

$$R_n = K_c K_h K_s N_s P_t \quad (6.13.2.8-1)$$

where:

K_c = creep factor taken equal to 0.80 for Class C galvanized faying surfaces or for duplex-coated faying surfaces utilizing a coating over a galvanized subsurface, and taken equal to 1.0 for all other surface conditions

K_h = hole size factor specified in Table 6.13.2.8-2

C6.13.2.8

Extensive data developed through research has been statistically analyzed to provide improved information on slip probability of connections in which the bolts have been pretensioned to the requirements of Table 6.13.2.8-1.

Two principal variables, bolt pretension and coefficient of friction, i.e., the surface condition factor of the faying surfaces, were found to have the greatest effect on the slip resistance of connections. Hole size factors less than 1.0 are provided for bolts in oversize and slotted holes because of their effects on the induced tension in bolts using any of the specified installation methods. In the case of bolts in long-slotted holes, even though the

- K_s = surface condition factor, specified in Table 6.13.2.8-3
 N_s = number of slip planes per bolt
 P_t = minimum required bolt tension, specified in Table 6.13.2.8-1 (kip)

Table 6.13.2.8-1—Minimum Required Tension for High-Strength Bolts

Nominal Bolt Diameter, in.	Required Tension- P_t (kip)	
	Specified Minimum Tensile Strength of 120 ksi	Specified Minimum Tensile Strength of 144 ksi ^a or 150 ksi
$5/8$	19	24
$3/4$	28	35
$7/8$	39	49
1	51	64
1 $1/8$	64	80
1 $1/4$	81	102
1 $3/8$	97	121
1 $1/2$	118	148

^aASTM F3148 Grade 144 bolts are only available in diameters of 1.25 in. or less.

Table 6.13.2.8-2—Values of K_h

For standard holes	1.00
For oversize and short-slotted holes	0.85
For long-slotted holes with the slot perpendicular to the direction of the force	0.70
For long-slotted holes with the slot parallel to the direction of the force	0.60

Table 6.13.2.8-3—Values of K_s

For Class A surface conditions	0.30
For Class B surface conditions	0.50
For Class C surface conditions	0.30
For Class D surface conditions	0.45

The following descriptions of surface condition shall apply to Table 6.13.2.8-3:

- Class A Surface: unpainted clean mill scale, and blast-cleaned surfaces with Class A coatings;
- Class B Surface: unpainted blast-cleaned surfaces to SSPC-SP 6 or better, and blast-cleaned surfaces with Class B coatings, or unsealed pure zinc or 85/15 zinc/aluminum thermal-sprayed coatings with a thickness less than or equal to 16 mils;
- Class C Surface: hot-dip galvanized surfaces; and

slip load is the same for bolts loaded transverse or parallel to the axis of the slot, the values for bolts loaded parallel to the axis have been further reduced, based upon judgment, because of the greater consequences of slip.

The criteria for slip resistance are for the case of connections subject to a coaxial load. For cases in which the load tends to rotate the connection in the plane of the faying surface, a modified formula accounting for the placement of bolts relative to the center of rotation should be used (Kulak et al., 1987).

The minimum bolt tension values given in Table 6.13.2.8-1 are equal to 70 percent of the minimum tensile strength for 120 ksi and 150 ksi bolts. Minimum bolt tension values for bolts with a minimum tensile strength of 144 ksi are the same as for 150 ksi bolts for convenience.

- Class D Surface: blast-cleaned surfaces with Class D coatings, or a mixed faying surface utilizing an unsealed pure zinc or 85/15 zinc/aluminum thermal-sprayed coating with a thickness less than or equal to 16 mils mating with a hot-dip galvanized surface.

The contract documents shall specify that in uncoated joints, paint, including any inadvertent overspray, be excluded from areas closer than one bolt diameter but not less than 1.0 in. from the edge of any hole and all areas within the bolt pattern.

The contract documents shall specify the minimum required value of the surface condition factor.

The effect of ordinary paint coatings on limited portions of the contact area within joints and the effect of overspray over the total contact area have been investigated experimentally (Polyzois and Frank, 1986). The tests demonstrated that the effective area for transfer of shear by friction between contact surfaces was concentrated in an annular ring around and close to the bolts. Paint on the contact surfaces approximately 1.0 in., but not less than the bolt diameter away from the edge of the hole did not reduce the slip resistance. On the other hand, bolt pretension might not be adequate to completely flatten and pull thick material into tight contact around every bolt. Therefore, these Specifications require that all areas between bolts also be free of paint.

On clean mill scale, this research found that even the smallest amount of overspray of ordinary paint, e.g., a coating not qualified as Class A, within the specified paint-free area, reduced the slip resistance significantly. On blast-cleaned surfaces, the presence of a small amount of overspray was not as detrimental. For simplicity, these Specifications prohibit any overspray from areas required to be free of paint in slip-critical joints, regardless of whether the surface is clean mill scale or blast-cleaned.

The mean value of slip coefficients from many tests on clean mill scale, blast-cleaned steel surfaces, unsealed thermal sprayed surfaces, zinc-rich primers, and galvanized and roughened surfaces were taken as the basis for the four classes of surfaces. As a result of research by Frank and Yura (1981), a test method to determine the slip coefficient for coatings used in bolted joints was developed (RCSC, 2020). The method includes long-term creep test requirements to ensure reliable performance for qualified coatings. The method, which requires requalification if an essential variable is changed, is the sole basis for qualification of any coating to be used under these Specifications.

In previous Specifications, only three categories of surface conditions to be used in slip-critical joints were recognized: Class A for unpainted clean mill scale and for blast-cleaned surfaces with coatings that do not reduce the slip coefficient below that provided by clean mill scale, Class B for unpainted blast-cleaned surfaces and for coatings that do not reduce the slip coefficient below that of blast-cleaned steel surfaces, and Class C for hot-dipped galvanized surfaces. Further research has found that hot-dip galvanized surfaces and clean mill scale demonstrate the same slip coefficients (Donahue et al., 2014); however, to avoid confusion, the separate categories are maintained. Class D has been added to increase the options for organic zinc-rich coatings (Ocel et al., 2014).

Metalized surfaces are often sealed with low-viscosity epoxy coatings, e.g., penetrating sealers, to fill the pores of the metalizing and enhance their corrosion

Subject to the approval of the Engineer, coatings providing a surface condition factor less than 0.30 may be used, provided that the mean surface condition factor is established by test. The nominal slip resistance shall be determined as the nominal slip resistance for Class A surface conditions, as appropriate for the hole and bolt type, times the surface condition factor determined by test divided by 0.30.

The contract documents shall specify that:

- Coated joints not be assembled before the coatings have cured for the minimum time used in the qualifying test, and
- Faying surfaces specified to be galvanized shall be hot-dip galvanized in accordance with AASHTO M 111M/M 111 (ASTM A123/A123M). No subsequent treatment of the galvanized surface is required.

If a slip-critical connection is subject to an applied tensile force that reduces the net clamping force, the nominal slip resistance shall be multiplied by the factor specified by Eq. 6.13.2.11-3.

resistance. Unsealed pure zinc and 85/15 zinc/aluminum thermal-sprayed surfaces are classified as Class B surfaces since they comfortably satisfy the Class B requirements (Annan and Chiza, 2014) (Ocel, 2014) when the thickness of the coating is less than or equal to 16 mils. Thermal-sprayed coatings can theoretically be applied to any thickness, although little to no slip performance data has been generated on coating thicknesses over 16 mils; hence, the restriction on coating thickness. Slip tests of some sealed thermal-sprayed coatings produced very low slip coefficients, or failed the creep requirement, and therefore are not included in the specification provisions.

Any other faying surface preparation not described in the specification, e.g., sealed thermal-sprayed coatings, thermal-sprayed coatings thicker than 16 mils, zinc-rich primer over hot-dip galvanizing, etc., can be qualified to one of the surface condition classifications in accordance with Appendix A of RCSC (2020) and may be used subject to the approval of the Engineer.

To cover those cases where a coefficient of friction less than 0.30 might be adequate, the Specification provides that, subject to the approval of the Engineer, and provided that the mean slip coefficient is determined by the specified test procedure, faying surface coatings providing lower slip resistance than a Class A coating may be used. Blast cleaning for the purposes of this Article means the removal of all mill scale. The minimum SSPC blast cleaning standard that will remove all mill scale is SSPC-SP 6. Tightly adhering rust that forms after blast cleaning will not reduce the slip coefficient. Most high-performance coatings require blast cleaning to near-white metal, or SSPC-SP 10.

The research cited above also investigated the effect of varying the time from coating the faying surfaces to assembly to ascertain if partially cured paint continued to cure. It was found that all curing ceased at the time the joint was assembled and tightened and that paint coatings that were not fully cured acted as lubricant. Thus, the slip resistance of the joint was severely reduced.

Research by Donahue et al. (2014) found that the slip coefficient of galvanized steel surfaces was sensitive to the silicon content of the steel. Structural steels with low silicon content had lower slip coefficients than steels with higher silicon content. The lower silicon steels produced a pure zinc layer with a lower slip coefficient. Treating the surface of the galvanized specimens did not improve the slip coefficient. The specified slip coefficient of 0.30 is a lower bound based upon tests of bridge steels without any surface treatment and with varying silicon contents after galvanizing.

The thickness of hot-dip galvanizing on faying surfaces is not limited herein. Instead, the nominal slip resistance for a bolt in a slip-critical connection with a Class C galvanized faying surface, or with a duplex coated faying surface utilizing a coating producing a higher slip coefficient over a galvanized subsurface, is reduced by 20 percent using the creep factor, K_c . The

creep of the galvanized surfaces within the grip of the bolt results in a loss of bolt tension, which is accounted for by the 20 percent reduction in the design nominal slip resistance. A similar creep loss occurs for both duplex coated faying surfaces and for galvanized faying surfaces alone. Studies show a maximum pretension loss of about 18 percent with plate galvanizing thicknesses up to 20 mils (DeWolf and Yang, 1998) (Donahue et al., 2014). Hot-dip galvanizing thicknesses exceeding 15 mils generally occur with more reactive steel and higher iron content makes them less compressible than thinner coatings on less reactive steel, so the percentage of pretension loss tends to be stable with thicker coatings. The slip coefficient of duplex coated systems would need to be established by test.

Annan and Chiza (2014) found that mixed faying surfaces utilizing an unsealed pure zinc thermal-sprayed coating mating with a hot-dip galvanized surface satisfy the Class D requirements. Ampleman et al. (2016) showed good creep performance of mixed faying surfaces between a 12.5-mil-thick thermal-sprayed coating and a 14-mil-thick galvanized coating for a slip coefficient of 0.45 using the test methods given in Appendix A of RCSC (2020). It is recommended that the current 16-mil limit on the thickness of the thermal-sprayed coating be applied for all thermal-sprayed coatings on faying surfaces of bolted connections. Until further tests are conducted with softer galvanized coatings on nonreactive steels, the creep factor, K_c , of 0.80 should also be conservatively applied in Eq. 6.13.2.8-1 when determining the nominal slip resistance of all connections with one or more galvanized faying surfaces.

While slip-critical connections with bolts pretensioned to the levels specified in Table 6.13.2.8-1 do not ordinarily slip into bearing when subject to anticipated loads, it is required that they meet the requirements of Article 6.13.2.7 and Article 6.13.2.9 in order to maintain a factor of safety of 2.0, if the bolts slip into bearing as a result of large, unforeseen loads.

6.13.2.9—Bearing Resistance at Bolt Holes

The effective bearing area of a bolt shall be taken as its diameter multiplied by the thickness of the connected material on which it bears. The effective thickness of connected material with countersunk holes shall be taken as the thickness of the connected material, minus one-half the depth of the countersink.

For standard holes, oversize holes, short-slotted holes loaded in any direction, and long-slotted holes parallel to the applied bearing force, the nominal resistance of interior and end bolt holes at the strength limit state, R_n , shall be taken as:

- With bolts spaced at a clear distance between holes not less than $2.0d$ and with a clear end distance not less than $2.0d$:

C6.13.2.9

Bearing stress produced by a high-strength bolt pressing against the side of the hole in a connected part is important only as an index to behavior of the connected part. Thus, the same bearing resistance applies regardless of bolt shear strength or the presence or absence of threads in the bearing area. The critical value can be derived from the case of a single bolt at the end of a tension member.

Using finger-tight bolts, it has been shown that a connected plate will not fail by tearing through the free edge of the material if the distance, L , measured parallel to the line of applied force from a single bolt to the free edge of the member toward which the force is directed, is not less than the diameter of the bolt multiplied by the ratio of the bearing stress to the tensile strength of the connected part (Kulak et al., 1987).

$$R_n = 2.4dtF_u \quad (6.13.2.9-1)$$

The criterion for nominal bearing strength is:

- If either the clear distance between holes is less than $2.0d$, or the clear end distance is less than $2.0d$:

$$\frac{L}{d} \geq \frac{r_n}{F_u} \quad (C6.13.2.9-1)$$

$$R_n = 1.2L_c t F_u \quad (6.13.2.9-2)$$

where:

For long-slotted holes perpendicular to the applied bearing force:

r_n = nominal bearing pressure (ksi)

F_u = specified minimum tensile strength of the connected part (ksi)

- With bolts spaced at a clear distance between holes not less than $2.0d$ and with a clear end distance not less than $2.0d$:

$$R_n = 2.0dtF_u \quad (6.13.2.9-3)$$

- If either the clear distance between holes is less than $2.0d$, or the clear end distance is less than $2.0d$:

$$R_n = L_c t F_u \quad (6.13.2.9-4)$$

where:

d = nominal diameter of the bolt (in.)

t = thickness of the connected material (in.)

F_u = tensile strength of the connected material specified in Table 6.4.1-1 (ksi)

L_c = clear distance between holes or between the hole and the end of the member in the direction of the applied bearing force (in.)

In these Specifications, the nominal bearing resistance of an interior hole is based on the clear distance between the hole and the adjacent hole in the direction of the bearing force. The nominal bearing resistance of an end hole is based on the clear distance between the hole and the end of the member. The nominal bearing resistance of the connected member may be taken as the sum of the smaller of the nominal shear resistance of the individual bolts and the nominal bearing resistance of the individual bolt holes parallel to the line of the force. The clear distance is used to simplify the computations for oversize and slotted holes.

Holes may be spaced at clear distances less than the specified values, as long as the lower value specified by Eq. 6.13.2.9-2 or Eq. 6.13.2.9-4, as applicable, is used for the nominal bearing resistance.

If the nominal bearing resistance of a bolt hole exceeds the nominal shear resistance of the bolt determined as specified in Article 6.13.2.7, the nominal bearing resistance of the bolt hole shall be limited to the nominal shear resistance of the bolt.

6.13.2.10—Tensile Resistance

6.13.2.10.1—General

High-strength bolts subjected to axial tension shall be tensioned to the force specified in Table 6.13.2.8-1. The applied tensile force shall be taken as the force due to the external factored loadings, plus any tension resulting from prying action produced by deformation of the connected parts, as specified in Article 6.13.2.10.4.

6.13.2.10.2—Nominal Tensile Resistance

The nominal tensile resistance of a bolt, T_n , independent of any initial tightening force shall be taken as:

$$T_n = 0.76 A_b F_{ub} \quad (6.13.2.10.2-1)$$

where:

A_b = area of bolt corresponding to the nominal diameter (in.²)

F_{ub} = specified minimum tensile strength of the bolt, specified in Article 6.4.3.1.1 (ksi)

6.13.2.10.3—Fatigue Resistance

Where high-strength bolts in axial tension are subject to fatigue, the stress range, Δf , in the bolt, due to the fatigue design live load, plus the dynamic load allowance for fatigue loading specified in Article 3.6.1.4, plus the prying force resulting from cyclic application of the fatigue load, shall satisfy Eq. 6.6.1.2.2-1.

The nominal diameter of the bolt shall be used in calculating the bolt stress range. In no case shall the calculated prying force exceed 30 percent of the externally applied load.

Low-carbon ASTM A307 bolts shall not be used in connections subjected to fatigue.

6.13.2.10.4—Prying Action

The tensile force due to prying action shall be taken as:

$$Q_u = \left[\frac{3b}{8a} - \frac{t^3}{20} \right] P_u \quad (6.13.2.10.4-1)$$

where:

Q_u = prying tension per bolt due to the factored loadings, taken as zero when negative (kip)

P_u = direct tension per bolt due to the factored loadings (kip)

a = distance from center of bolt to edge of plate (in.)

b = distance from center of bolt to the toe of fillet of connected part (in.)

t = thickness of thinnest connected part (in.)

6.13.2.11—Combined Tension and Shear

The nominal tensile resistance of a bolt subjected to combined shear and axial tension, T_n , shall be taken as:

- If $\frac{P_u}{R_n} \leq 0.33$, then:

$$T_n = 0.76 A_b F_{ub} \quad (6.13.2.11-1)$$

- Otherwise:

C6.13.2.10.2

The recommended design strength is approximately equal to the initial tightening force; thus, when loaded to the service load, high-strength bolts will experience little, if any, actual change in stress. For this reason, bolts in connections, in which the applied loads subject the bolts to axial tension, are required to be fully tensioned.

C6.13.2.10.3

Properly tightened high-strength bolts are not adversely affected by repeated application of the recommended service load tensile stress, provided that the fitting material is sufficiently stiff that the prying force is a relatively small part of the applied tension. The provisions covering bolt tensile fatigue are based upon study of test reports of bolts that were subjected to repeated tensile load to failure (Kulak et al., 1987).

C6.13.2.10.4

Eq. 6.13.2.10.4-1 for estimating the magnitude of the force due to prying is a simplification given in ASCE (1971) of a semiempirical expression (Douty and McGuire, 1965). This simplified formula tends to overestimate the prying force and provides conservative design results (Nair et al., 1974).

C6.13.2.11

The nominal tensile resistance of bolts subject to combined axial tension and shear is provided by elliptical interaction curves, which account for the connection length effect on bolts loaded in shear, the ratio of shear strength to tension strength of threaded bolts, and the ratios of root area to nominal body area and tensile stress area to nominal body area (Chesson et al., 1965). Eqs. 6.13.2.11-1 and 6.13.2.11-2 are conservative simplifications of the set of elliptical curves. The

$$T_n = 0.76 A_b F_{ub} \sqrt{1 - \left(\frac{P_u}{\phi_s R_n} \right)^2} \quad (6.13.2.11-2)$$

where:

- A_b = area of the bolt corresponding to the nominal diameter (in.²)
 F_{ub} = specified minimum tensile strength of the bolt, specified in Article 6.4.3.1.1 (ksi)
 P_u = shear force on the bolt due to the factored loads (kip)
 R_n = nominal shear resistance of a bolt, specified in Article 6.13.2.7 (kip)

The nominal resistance of a bolt in slip-critical connections under Load Combination Service II, specified in Table 3.4.1-1, subjected to combined shear and axial tension, shall not exceed the nominal slip resistance specified in Article 6.13.2.8 multiplied by:

$$1 - \frac{T_u}{K_c P_t} \quad (6.13.2.11-3)$$

where:

- K_c = creep factor, taken equal to 0.80 for Class C galvanized faying surfaces or for duplex-coated faying surfaces utilizing a coating over a galvanized subsurface, and taken equal to 1.0 for all other surface conditions
 T_u = tensile force due to the factored loads under Load Combination Service II (kip)
 P_t = minimum required bolt tension, specified in Table 6.13.2.8-1 (kip)

6.13.2.12—Shear Resistance of Anchor Rods

The nominal shear resistance of an ASTM F1554 anchor rod at the strength limit state shall be taken as:

$$R_n = 0.50 A_b F_{ub} N_s \quad (6.13.2.12-1)$$

where:

- A_b = area of the anchor rod corresponding to the nominal diameter (in.²)
 F_{ub} = specified minimum tensile strength of the anchor rod (ksi)
 N_s = number of shear planes per anchor rod

equations representing the set of elliptical curves for various cases may be found in AISC (1988). No reduction in the nominal tensile resistance is required when the applied shear force on the bolt due to the factored loads is less than or equal to 33 percent of the nominal shear resistance of the bolt.

C6.13.2.12

Eq. 6.13.2.12-1 assumes threads are included in the shear plane since the thread length of anchor rods is not limited by the specification. See Article C6.13.2.7 for further commentary on Eq. 6.13.2.12-1. The joint length effect is not applicable to anchor rods.

For global design of anchorages to concrete, refer to *Building Code Requirements for Structural Concrete* (ACI 318-14).

6.13.3—Welded Connections**6.13.3.1—General**

Base metal, weld metal, and welding design details shall conform to the requirements of the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*. Welding symbols shall conform to those specified in AWS A2.4.

Matching weld metal shall be used in groove and fillet welds, except that the Engineer may specify electrode classifications with strengths less than the base metal when detailing fillet welds, in which case the welding procedure and weld metal shall be selected to ensure sound welds.

6.13.3.2—Factored Resistance**6.13.3.2.1—General**

The factored resistance of welded connections, R_r , at the strength limit state shall be taken as specified in Articles 6.13.3.2.2 through 6.13.3.2.4.

The effective area of the weld shall be taken as specified in Article 6.13.3.3. The factored resistance of the connection material shall be taken as specified in Article 6.13.5.

6.13.3.2.2—Complete Joint Penetration Groove-Welded Connections**6.13.3.2.2a—Tension and Compression**

The factored resistance of complete joint penetration groove-welded connections subjected to tension or compression normal to the effective area or parallel to the axis of the weld shall be taken as the factored resistance of the base metal.

6.13.3.2.2b—Shear

The factored resistance of complete joint penetration groove-welded connections subjected to shear on the effective area shall be taken as the lesser of the value given by Eq. 6.13.3.2.2b-1 or 60 percent of the factored resistance of the base metal in tension:

$$R_r = 0.6\phi_e F_{exx} \quad (6.13.3.2.2b-1)$$

where:

C6.13.3.1

Matching weld metal has a specified minimum tensile strength that is the same as or higher than the lower-strength base metal. Matching strengths for various weld and base metal combinations are specified in the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*.

Use of undermatched weld metal is highly encouraged for fillet welds connecting steels with specified minimum yield strength greater than 50 ksi. Research has shown that undermatched welds are much less sensitive to delayed hydrogen cracking and are more likely to produce sound welds on a consistent basis.

C6.13.3.2.1

The factored resistance of a welded connection is governed by the resistance of the base metal or the deposited weld metal. The nominal resistance of fillet welds is determined from the effective throat area, whereas the nominal strength of the connected parts is governed by their respective thickness.

The classification strength of the weld metal, F_{exx} , in the articles that follow, is taken as the specified minimum tensile strength of the weld metal in ksi, which is reflected in the classification designation of the electrode. For example, the “70” in E70XX (SMAW), ER70S (solid-wire GMAW), and E70C (metal-cored GMAW); and the “7” in E71XX (FCAW) and F7XX (SAW) indicate a specified minimum tensile strength of 70.0 ksi.

C6.13.3.2.2a

In groove welds, the maximum forces are usually tension or compression. Tests have shown that groove welds of the same thickness as the connected parts are adequate to develop the factored resistance of the connected parts.

F_{exx} = classification strength of the weld metal (ksi)
 ϕ_{e1} = resistance factor for the weld metal, specified in Article 6.5.4.2

6.13.3.2.3—Partial Joint Penetration Groove-Welded Connections

6.13.3.2.3a—Tension or Compression

The factored resistance of partial joint penetration groove-welded connections subjected to tension or compression parallel to the axis of the weld or compression normal to the effective area shall be taken as the factored resistance of the base metal.

The factored resistance for partial joint penetration groove-welded connections subjected to tension normal to the effective area shall be taken as the lesser of either the value given by either Eq. 6.13.3.2.3a-1 or the factored resistance of the base metal:

$$R_r = 0.6\phi_{e1}F_{exx} \quad (6.13.3.2.3a-1)$$

where:

ϕ_{e1} = resistance factor for the weld metal, specified in Article 6.5.4.2

6.13.3.2.3b—Shear

The factored resistance of partial joint penetration groove-welded connections subjected to shear parallel to the axis of the weld shall be taken as the lesser of either the factored nominal resistance of the connected material specified in Article 6.13.5 or the factored resistance of the weld metal taken as:

$$R_r = 0.6\phi_{e2}F_{exx} \quad (6.13.3.2.3b-1)$$

where:

ϕ_{e2} = resistance factor for the weld metal, as specified in Article 6.5.4.2

6.13.3.2.4—Fillet-Welded Connections

The resistance of fillet welds which are made with matched or undermatched weld metal and which have typical weld profiles shall be taken as the smaller of the factored shear rupture resistance of the connected material adjacent to the weld leg determined as specified in Article 6.13.5.3, and the product of the effective area specified in Article 6.13.3.3 and the factored shear resistance of the weld metal taken as:

$$R_r = 0.6\phi_{e2}F_{exx} \quad (6.13.3.2.4-1)$$

C6.13.3.2.3a

Eq. 6.6.1.2.5-4 should also be considered in the fatigue design of partial joint penetration groove-welded connections subject to tension.

C6.13.3.2.4

The factored resistance of fillet welds is based on the assumption that failure of such welds is by shear on the effective area whether the shear transfer is parallel or perpendicular to the axis of the line of the weld. In fact, the resistance is greater for shear transfer perpendicular to the weld axis; however, for simplicity the situations are treated the same. Thus, the factored resistance of fillet welds may be controlled by the shear resistance of the weld metal or by the shear rupture resistance of the connected material.

Shear yielding is not critical in welds because the material strain hardens without large overall deformations occurring. Therefore, the factored shear resistance of the

weld metal is based on the shear resistance of the weld metal multiplied by a suitable resistance factor to ensure that the connected part will develop its full strength without premature failure of the weldment.

If fillet welds are subjected to eccentric loads that produce a combination of shear and bending stresses, they must be proportioned on the basis of a direct vector addition of the shear forces on the weld.

It is seldom that weld failure will ever occur at the weld leg in the base metal. The applicable effective area for the base metal is the weld leg which is 30 percent greater than the weld throat. If overstrength weld metal is used or the weld throat has excessive convexity, the capacity can be governed by the weld leg and the shear rupture resistance of the base metal.

6.13.3.3—Effective Area

The effective area shall be the effective weld length multiplied by the effective throat. The effective throat shall be the shortest distance from the joint root to the weld face.

6.13.3.4—Size of Fillet Welds

The size of a fillet weld that may be assumed in the design of a connection shall be such that the forces due to the factored loadings do not exceed the factored resistance of the connection specified in Article 6.13.3.2.

The maximum size of fillet weld that may be used along edges of connected parts shall be taken as:

- For material less than 0.25 in. thick: the thickness of the material, and
- For material 0.25 in. thick or more: 0.0625 in. less than the thickness of the material, unless the weld is designated on the contract documents to be built out to obtain full throat thickness.

The minimum size of fillet weld should be taken as specified in Table 6.13.3.4-1. The weld size need not exceed the thickness of the thinner part joined. Smaller fillet welds may be approved by the Engineer based upon applied stress and the use of the appropriate preheat.

Table 6.13.3.4-1—Minimum Size of Fillet Welds

Base Metal Thickness of Thicker Part Joined, T in.	Minimum Size of Fillet Weld in.
$T \leq \frac{3}{4}$	$\frac{1}{4}$
$\frac{3}{4} < T$	$\frac{5}{16}$

C6.13.3.3

Additional requirements can be found in the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*, Article 2.3.

C6.13.3.4

The requirements for minimum size of fillet welds are based upon the quench effect of thick material on small welds, not on strength considerations. Very rapid cooling of weld metal may result in a loss of ductility. Further, the restraint to weld metal shrinkage provided by thick material may result in weld cracking. A 0.3125-in. fillet weld is the largest that can be deposited in a single pass by manual process, but minimum preheat and interpass temperatures are to be provided.

6.13.3.5—Minimum Effective Length of Fillet Welds

The minimum effective length of a fillet weld shall be four times its size and in no case less than 1.5 in.

6.13.3.6—Fillet Weld End Returns

Fillet welds that resist a tensile force not parallel to the axis of the weld or that are not proportioned to withstand repeated stress shall not terminate at corners of parts or members. Where such returns can be made in the same plane, they shall be returned continuously, full size, around the corner, for a length equal to twice the weld size. End returns shall be indicated in the contract documents.

Fillet welds deposited on the opposite sides of a common plane of contact between two parts shall be interrupted at a corner common to both welds.

6.13.3.7—Fillet Welds for Sealing

Seal welds should be continuous welds combining the functions of sealing and strength. The portion of a return sealing fillet weld around the ends of a transverse, longitudinal or bearing stiffener, connection plate, or a lap splice connection shall be exempt from the minimum size requirements specified in Article 6.13.3.4, and shall not be considered in determining the resistance of the connection.

6.13.4—Block Shear Rupture Resistance

The web connection of coped beams and all tension connections, including connection plates, splice plates and gusset plates, shall be investigated to ensure that adequate connection material is provided to develop the factored resistance of the connection.

C6.13.3.6

Fillet welds satisfying the provisions of Article 6.13.3.7 may be wrapped around the end of a transverse, longitudinal or bearing stiffener, connection plate, or a lap splice connection for sealing. The welds may also be wrapped around the inside of the cope of a stiffener or a connection plate, if desired.

C6.13.3.7

Fillet welds wrapping the ends of a transverse, longitudinal or bearing stiffener, connection plate, or a lap splice connection, are simply for sealing and are not to be included in the calculation of the resistance of the connection. The undercutting of the corner of the stiffener or connection plate, even when severe, does not reduce the fatigue performance of the weld, which is controlled by the toe of the transverse fillet weld connecting the stiffener or connection plate to the flange (Spadea and Frank, 2004).

The ends of fillet-welded connections in galvanized structures, in particular, should be sealed to prevent the acids used to prepare the steel for galvanizing from being trapped in-between the components and then leaching out. Vent holes or an unwelded length around the adjoining surfaces should be provided to allow the trapped air and moisture to escape and prevent destructive pressures from developing between the surfaces if the overlapped area is greater than or equal to 16.0 in.² for plates 0.5 in. or less in thickness or greater than or equal to 64.0 in.² for plates greater than 0.5 in. in thickness. Tables 1 and 2 in ASTM A385/A385M provide further guidance along with the size of the vent holes or the unwelded length that is required when the overlapped area exceeds the preceding values.

C6.13.4

Block shear rupture is one of several possible failure modes for splices, connections, and gusset plates. Investigation of other failure modes and critical sections is still required, e.g., a net section extending across the full plate width, and, therefore, having no parallel planes, may be a more severe requirement for a girder flange or splice plate than the block shear rupture mode. The provisions of Articles 6.13.5, 6.13.6, and 6.14.2.8 should be consulted.

The connection shall be investigated by considering all possible failure planes in the member and connection plates. Such planes shall include those parallel and perpendicular to the applied forces. The planes parallel to the applied force shall be considered to resist only shear stresses. The planes perpendicular to the applied force shall be considered to resist only tension stresses.

The factored resistance of the combination of parallel and perpendicular planes shall be taken as:

$$R_r = \phi_{bs} R_p (0.58 F_u A_{vn} + U_{bs} F_u A_{tn}) \leq \phi_{bs} R_p (0.58 F_y A_{vg} + U_{bs} F_u A_{tn}) \quad (6.13.4-1)$$

where:

- R_p = reduction factor for holes, taken equal to 0.90 for bolt holes punched full size and 1.0 for bolt holes drilled full size or subpunched and reamed to size
- A_{vg} = gross area along the plane resisting shear stress (in.²)
- A_{vn} = net area along the plane resisting shear stress (in.²)
- U_{bs} = reduction factor for block shear rupture resistance, taken equal to 0.50 when the tension stress is nonuniform and 1.0 when the tension stress is uniform
- A_{tn} = net area along the plane resisting tension stress (in.²)
- F_y = specified minimum yield strength of the connected material (ksi)
- F_u = specified minimum tensile strength of the connected material, specified in Table 6.4.1-1 (ksi)
- ϕ_{bs} = resistance factor for block shear, specified in Article 6.5.4.2

The gross area shall be determined as the length of the plane multiplied by the thickness of the component. The net area shall be the gross area, minus the number of whole or fractional holes in the plane, multiplied by the nominal hole diameter specified in Table 6.13.2.4.2-1 times the thickness of the component.

In determining the net section of cuts carrying tension stress, the effect of staggered holes adjacent to the cuts shall be determined in accordance with Article 6.8.3. For net sections carrying shear stress, the full effective diameter of holes centered within two diameters of the cut shall be deducted. Holes further removed may be disregarded.

Tests on coped beams have indicated that a tearing failure mode can occur along the perimeter of the bolt holes (Birkemoe and Gilmour, 1978). This block shear failure mode is one in which the resistance is determined by the sum of the nominal shear resistance on a failure path(s) and the nominal tensile resistance on a perpendicular segment. The failure path is defined by the centerlines of the bolt holes. The block shear rupture mode is not limited to the coped ends of beams. Tension member connections are also susceptible. The block shear rupture mode should also be checked around the periphery of welded connections.

A conservative model has been adopted to predict the block shear rupture resistance in which the resistance to rupture along the shear plane is added to the resistance to rupture on the tensile plane. Block shear is a rupture or tearing phenomenon and not a yielding phenomenon. However, gross yielding along the shear plane can occur when tearing on the tensile plane commences if $0.58 F_u A_{vn}$ exceeds $0.58 F_y A_{vg}$. Therefore, Eq. 6.13.4-1 limits the term $0.58 F_u A_{vn}$ to not exceed $0.58 F_y A_{vg}$. Eq. 6.13.4-1 is consistent with the philosophy for tension members where the gross area is used for yielding and the net area is used for rupture.

In certain cases, e.g., coped beam connections with multiple rows of bolts, the tensile stress on the end plane is nonuniform because the rows of bolts nearest the beam end pick up most of the shear (Ricles and Yura, 1983) (Kulak and Grondin, 2001). Therefore, a reduction factor, U_{bs} , has been included in Eq. 6.13.4-1 to approximate the effect of the nonuniform stress distribution on the tensile plane in such cases. For the majority of connections encountered in steel bridges, U_{bs} will equal 1.0. The reduction factor, R_p , conservatively accounts for the reduced rupture resistance in the vicinity of bolt holes that are punched full size (Brown et al., 2007), as discussed further in Article C6.8.2.1.

6.13.5—Connection Elements

6.13.5.1—General

This Article shall be applied to the design of connection elements such as splice plates, gusset plates, corner angles, brackets, and lateral connection plates in tension or shear, as applicable.

6.13.5.2—Tension

The factored resistance, R_r , in tension shall be taken as the least of the values given by either Eqs. 6.8.2.1-1 and 6.8.2.1-2 for yielding and fracture, respectively, or the block shear rupture resistance specified in Article 6.13.4.

In determining the value of P_m as specified in Eq. 6.8.2.1-2, for lateral connection plates, splice plates, and gusset plates, the reduction factor, U , specified in Article 6.8.2.2, shall be taken to be equal to 1.0, except as specified in Case 4 of Table 6.8.2.2-1, and the net area of the plate, A_n , used in Eq. 6.8.2.1-2, shall not be taken as greater than 85 percent of the gross area of the plate.

6.13.5.3—Shear

The factored shear resistance, R_r , of the connection element shall be taken as the smaller value based on shear yielding or shear rupture.

For shear yielding, the factored shear resistance of the connection element shall be taken as:

$$R_r = \phi_v 0.58 F_y A_{vg} \quad (6.13.5.3-1)$$

where:

A_{vg} = gross area of the connection element subject to shear (in.²)

F_y = specified minimum yield strength of the connection element (ksi)

ϕ_v = resistance factor for shear, as specified in Article 6.5.4.2

For shear rupture, the factored shear resistance, R_r , of the connection element shall be taken as:

$$R_r = \phi_{vu} 0.58 R_p F_u A_{vn} \quad (6.13.5.3-2)$$

where:

A_{vn} = net area of the connection element subject to shear (in.²)

F_u = tensile strength of the connection element (ksi)

R_p = reduction factor for holes taken equal to 0.90 for bolt holes punched full size and 1.0 for bolt holes drilled full size or subpunched and reamed to size

C6.13.5.2

Because the length of the lateral connection plate, splice plate, or gusset plate is small compared to the member length, inelastic deformation of the gross section is limited. Hence, the net area of the connecting element is limited to $0.85A_g$ in recognition of the limited inelastic deformation and to provide a reserve capacity (Kulak et al., 1987).

ϕ_{vr} = resistance factor for shear rupture of connection elements, as specified in Article 6.5.4.2

6.13.6—Splices

6.13.6.1—Bolted Splices

6.13.6.1.1—Tension Members

Splices for tension members shall be designed at the strength limit state to satisfy the requirements specified in Article 6.13.1. Where a section changes at a splice, the smaller of the two connected sections shall be used in the design. Splices for tension members shall also satisfy the requirements specified in Article 6.13.5.2. Splices for tension members shall be designed using slip-critical connections as specified in Article 6.13.2.1.1.

6.13.6.1.2—Compression Members

Except as specified herein, splices for compression members shall be designed at the strength limit state to satisfy the requirements specified in Article 6.13.1. Where a section changes at a splice, the smaller of the two connected sections shall be used in the design. Splices for compression members detailed with milled ends in full contact bearing at the splices and for which the contract documents specify inspection during fabrication and erection, may be proportioned for not less than 50 percent of the lower factored resistance of the sections spliced.

Splices in truss chords, arch members, and columns should be located as near to the panel points as practicable and usually on that side where the smaller force effect occurs. The arrangement of plates, angles, or other splice elements shall be such as to make proper provision for all force effects in the component parts of the members spliced.

6.13.6.1.3—Flexural Members

6.13.6.1.3a—General

In continuous spans, splices should be made at or near points of dead load contraflexure. Web and flange splices in areas of stress reversal shall be investigated for both positive and negative flexure.

Flange splices shall be designed as specified in Article 6.13.6.1.3b and web splices shall be designed as specified in Article 6.13.6.1.3c. In both web and flange splices, there shall not be less than two rows of bolts on each side of the joint. Oversize or slotted holes shall not be used in either the member or the splice plates at bolted splices.

Bolted splices for flexural members shall be designed using slip-critical connections as specified in Article 6.13.2.1.1. The connections shall also be proportioned to prevent slip during the casting of the concrete deck.

C6.13.6.1.2

This is consistent with the provisions of past editions of the *AASHTO Standard Specifications for Highway Bridges* (2002), which permitted up to 50 percent of the force in a compression member to be carried through a splice by bearing on milled ends of components.

C6.13.6.1.3a

The method for the design of bolted splices for flexural members specified herein is based in principle on an alternative method first suggested by Sheikh-Ibrahim and Frank (1998, 2001) whereby all the factored moment is assumed to be resisted by the flange splices, provided the flange splices are capable of resisting the moment. Should the factored moment exceed the moment resistance provided by the flange splices, the web splice is assumed to resist the additional moment in addition to its design shear. The primary difference in this approach versus previous approaches is that the moment due to the eccentricity of the shear is ignored in the method specified herein.

Bolted splices located in regions of stress reversal near points of dead load contraflexure must be checked for both positive and negative flexure to determine the governing condition.

The factored flexural resistance of the flanges at the point of splice at the strength limit state shall satisfy the applicable provisions of Articles 6.10.6.2 or 6.11.6.2.

To ensure proper alignment and stability of the girder during construction, web and flange splices are not to have less than two rows of bolts on each side of the joint. Also, oversize or slotted holes are not permitted in either the member or the splice plates at bolted splices of flexural members for improved geometry control during erection and because a strength reduction may occur when oversize or slotted holes are used in eccentrically loaded bolted web connections.

Also, for improved geometry control, bolted connections for both web and flange splices are to be proportioned to prevent slip under the maximum actions induced during the casting of the concrete deck.

Eq. 6.10.1.8-1 provides a limit on the maximum factored major-axis bending stress permitted on the gross section of the girder, neglecting the loss of area due to holes in the tension flange at the bolted splice. Eq. 6.10.1.8-1 will prevent a bolted splice from being located at a section where the factored flexural resistance of the section at the strength limit state exceeds the moment at first yield, M_y , unless the factored stress in the tension flange at that section is limited to the value given by the equation.

Since the combined areas of the flange and web splice plates will typically equal or exceed the areas of the smaller web and flange to which they are attached, and the flange and web are checked separately for either equivalent or more critical fatigue category details, fatigue of the base metal adjacent to the slip-critical connections in the splice plates will not control the design of the splice plates.

6.13.6.1.3b—Flange Splices

Flange splice plates and their connections shall be designed to develop the smaller design yield resistance of the flanges on either side of the splice. The design yield resistance of each flange, P_{fy} , at the point of splice shall be taken as:

$$P_{fy} = F_y A_e \quad (6.13.6.1.3b-1)$$

in which:

A_e = effective area of the flange under consideration (in.²). A_e shall be taken as:

$$A_e = \left(\frac{\phi_u F_u}{\phi_y F_y} \right) A_n \leq A_g \quad (6.13.6.1.3b-2)$$

where:

ϕ_u = resistance factor for fracture of tension members, as specified in Article 6.5.4.2
 ϕ_y = resistance factor for yielding of tension members, as specified in Article 6.5.4.2

C6.13.6.1.3b

To determine whether threads are excluded from or included in the shear planes in the calculation of the factored shear resistance of the bolts, consult the suggested guidance provided in Article C6.13.2.7. For flange splices, it is typically found that threads will be excluded from the shear planes based on this guidance.

The use of the effective flange area in the computation of P_{fy} accounts for the loss in section causing a reduction in the fracture resistance of the net section at the connection for loading conditions in which the flange is subject to tension. The effective flange area is conservatively used for both tension and compression flanges. The load-shedding factor, R_b , and the hybrid factor, R_h , are not included in the equation for P_{fy} since the effect of the load shedding due to local web buckling and due to early local yielding of the lower-strength web is considered in the design of the girder flanges at the point of splice through the application of R_b and R_h to reduce the nominal flexural resistance of the flanges below F_y .

Figure C6.13.6.1.3b-1 illustrates the computation of the moment resistance provided by the flanges at the strength limit state, neglecting the contribution from the web and considering only the flange force, for composite sections subject to positive flexure at the strength limit

- A_n = net area of the flange under consideration, determined as specified in Article 6.8.3 (in.²)
 A_g = gross area of the flange under consideration (in.²)
 F_u = specified minimum tensile strength of the flange under consideration, determined as specified in Table 6.4.1-1 (ksi)
 F_{yf} = specified minimum yield strength of the flange under consideration (ksi)

For each flange, the smaller design yield resistance at the point of splice, P_{fy} , shall be divided by the factored shear resistance of the bolts, determined as specified in Article 6.13.2.2, to determine the total number of flange splice bolts required on one side of the splice at the strength limit state. Where filler plates are required, the provisions of Article 6.13.6.1.4 shall apply. The bearing resistance of the flange splice bolt holes shall also be checked at the strength limit state as specified in Article 6.13.2.9.

The moment resistance provided by the flanges at the point of splice shall be checked against the factored moment at the strength limit state. Should the factored moment exceed the moment resistance provided by the flanges, the additional moment shall be resisted by the web as specified in Article 6.13.6.1.3c. For composite sections subject to positive flexure, the moment resistance provided by the flanges at the strength limit state shall be computed as P_{fy} for the bottom flange times the moment arm taken as the vertical distance from the mid-thickness of the bottom flange to the mid-thickness of the concrete deck including the concrete haunch. For composite sections subject to negative flexure and noncomposite sections subject to positive or negative flexure, the moment resistance provided by the flanges shall be computed as P_{fy} for the top or bottom flange, whichever is smaller, times the moment arm taken as the vertical distance between the mid-thickness of the top and bottom flanges.

At the strength limit state, the design force in the splice plates shall not exceed the factored resistance in tension specified in Article 6.13.5.2.

The moment resistance provided by the nominal slip resistance of the flange splice bolts that are required to satisfy the strength limit state shall be checked against the factored moment for checking slip. The nominal slip resistance of the flange splice bolts shall be determined as specified in Article 6.13.2.8. Should the factored moment exceed the moment resistance provided by the nominal slip resistance of the flange splice bolts, the additional moment shall be resisted by the web as specified in Article 6.13.6.1.3c. The factored moments for checking slip shall be taken as the moment at the point of splice under Load Combination Service II, as specified in Table 3.4.1-1, and also the factored moment at the point of splice due to the deck placement sequence as specified in Article 6.10.3.1.

For the following box sections:

state. The moment resistance is taken equal to P_{fy} for the bottom flange times the moment arm, A , where the thickness of the concrete haunch is assumed measured from the top of the web to the bottom of the concrete deck:

Moment resistance is equal to P_{fy} for the bottom flange times the moment arm, A .

Figure C6.13.6.1.3b-1—Calculation of the Moment Resistance Provided by the Flanges for Composite Sections Subject to Positive Flexure

Figure C6.13.6.1.3b-2 illustrates the computation of the moment resistance provided by the flanges at the strength limit state for composite sections subject to negative flexure and noncomposite sections at the strength limit state taken equal to P_{fy} for the top or bottom flange, whichever is smaller, times the moment arm, A :

Moment resistance is equal to $P_{fy(top)}$ or $P_{fy(bot)}$, whichever is smaller, times the moment arm, A .

Figure C6.13.6.1.3b-2—Calculation of the Moment Resistance Provided by the Flanges for Composite Sections Subject to Negative Flexure and Noncomposite Sections

For composite sections where:

- shear connectors are provided in regions of negative flexure such that the longitudinal reinforcement may

- single box sections in straight bridges;
- multiple box sections in straight bridges not satisfying the requirements of Article 6.11.2.3;
- single or multiple box sections in horizontally curved bridges; or
- single or multiple box sections with box flanges that are not fully effective according to the provisions of Article 6.11.1.1,

the vector sum of the St. Venant torsional shear in the bottom flange and P_{fy} shall be considered in the design of the bottom flange splice at the strength limit state. For checking slip, the St. Venant torsional shear shall be subtracted from the nominal slip resistance of the bottom flange splice bolts prior to computing the moment resistance.

be considered part of the composite section, as permitted in Article 6.10.10.1; and

- the longitudinal reinforcement is considered in the section properties for calculating flexural stresses acting on composite sections subject to negative flexure as specified in Article 6.10.1.1.c, or for computing the factored moment resistance of the composite section in negative flexure, as applicable,

the moment resistance provided by the flanges at the strength limit state at the point of splice for composite sections subject to negative flexure can potentially be increased if desired. This increase, which will allow the design of the bolted splice to be compatible with the moment design of the section when the longitudinal reinforcement is included in the moment design of the section, may be accomplished by including the additional moment resistance provided by the design yield resistance of the longitudinal deck reinforcement, P_{rs} , which is defined as follows:

$$P_{rs} = A_{rs}F_{yr} \quad (\text{C6.13.6.1.3b-1})$$

where:

A_{rs} = total area of the longitudinal reinforcement included in the composite section satisfying the size, spacing, and placement requirements, specified in Article 6.10.1.7, but not to exceed one percent of the total cross-sectional area of the concrete deck assumed distributed within the appropriate effective width of the concrete deck acting with the girder under consideration (in.²)

F_{yr} = specified minimum yield strength of the longitudinal reinforcement: (ksi)

In determining the moment resistance provided by the longitudinal reinforcement, P_{rs} should be applied at the centroid of the longitudinal deck reinforcement. If the sum of P_{rs} and $P_{fy(top)}$ is smaller than $P_{fy(bot)}$, then the moment resistance is computed as the sum of P_{rs} and $P_{fy(top)}$ times the moment arm from the centroid of the combined area of P_{rs} and $P_{fy(top)}$ to the mid-thickness of the bottom flange. Otherwise, the moment resistance is computed as $P_{fy(bot)}$ times the moment arm from the mid-thickness of the bottom flange to the centroid of the combined area of P_{rs} and $P_{fy(top)}$.

The moment resistance provided by the flanges can potentially be increased by staggering the flange bolts.

When checking for slip, the moment resistance provided by the nominal slip resistance of the flange splice bolts is calculated as shown in Figures C6.13.6.1.3b-1 and C6.13.6.1.3b-2, with the appropriate nominal slip resistance of the flange splice bolts substituted for P_{fy} . For checking slip due to the factored

bending need not be considered in the design of the bolted flange splices since the combined areas of the flange splice plates will typically equal or exceed the area of the smaller flange to which they are attached. The flange is designed so that the yield stress of the flange is not exceeded at the flange tips under combined major-axis and lateral bending for constructibility and at the strength limit state. Flange lateral bending is also less critical at locations in-between the cross-frames or diaphragms where bolted splices are located. The rows of bolts provided in the flange splice on each side of the web provide the necessary couple to resist the lateral bending. Flange lateral bending will increase the flange slip force on one side of the splice and decrease the slip force on the other side of the splice; slip cannot occur unless it occurs on both sides of the splice.

6.13.6.1.3c—Web Splices

As a minimum, web splice plates and their connections shall be designed at the strength limit state for a design web force taken equal to the smaller factored shear resistance of the web, $V_r = \phi_v V_n$, on either side of the splice determined according to the provisions of Article 6.10.9 or 6.11.9, as applicable.

Should the moment resistance provided by the flanges at the point of splice, determined as specified in Article 6.13.6.1.3b, not be sufficient to resist the factored moment at the strength limit state, the web splice connections shall instead be designed for a design web force taken equal to the vector sum of the smaller factored shear resistance and a horizontal force in the web that provides the necessary moment resistance in conjunction with the flanges.

The horizontal force in the web shall be computed as the portion of the factored moment at the strength limit state at the point of splice that exceeds the moment resistance provided by the flanges divided by the appropriate moment arm. For composite sections subject to positive flexure, the moment arm shall be taken as the vertical distance from the mid-depth of the web to the mid-thickness of the concrete deck including the concrete haunch. For composite sections subject to negative flexure and noncomposite sections subject to positive or negative flexure, the moment arm shall be taken as one-quarter of the web depth.

The computed design web force shall be divided by the factored shear resistance of the bolts, determined as specified in Article 6.13.2.2, to determine the total number of web splice bolts required on one side of the splice at the strength limit state. The bearing resistance of the web at bolt holes shall also be checked at the strength limit state as specified in Article 6.13.2.9.

As a minimum, bolted connections for web splices shall be checked for slip under a web slip force taken equal to the factored shear in the web at the point of splice. Should the moment resistance provided by the nominal slip resistance of the flange splice bolts,

C6.13.6.1.3c

To determine whether threads are excluded from or included in the shear planes in the calculation of the factored shear resistance of the bolts, consult the suggested guidance provided in Article C6.13.2.7. For web splices, it may be found that threads are included in the shear planes based on this guidance. As a minimum, two vertical rows of bolts spaced at the maximum spacing for sealing bolts specified in Article 6.13.2.6.2 should be provided, with a closer spacing and/or additional rows provided only as needed.

Since the web splice is being designed to develop the full factored shear resistance of the web as a minimum at the strength limit state and the eccentricity of the shear is small relative to the depth of the connection, the effect of the small moment introduced by the eccentricity of the web connection may be ignored at all limit states. Also, for the box sections specified in Article 6.13.6.1.3b, the effect of the additional St. Venant torsional shear in the web may be ignored at the strength limit state since the web splice is being designed as a minimum for the full factored shear resistance of the web.

Figure C6.13.6.1.3c-1 illustrates the computation of the horizontal force in the web, H_w , where necessary for composite sections subject to positive flexure. The web moment is taken as the portion of the factored moment that exceeds the moment resistance provided by the flanges. H_w is then taken as the web moment divided by the moment arm, A_w , taken from the mid-depth of the web to the mid-thickness of the concrete deck including the concrete haunch.

determined as specified in Article 6.13.6.1.3b, not be sufficient to resist the factored moment for checking slip at the point of splice, the web splice bolts shall instead be checked for slip under a web slip force taken equal to the vector sum of the factored shear and a horizontal force in the web that provides the necessary slip resistance in conjunction with the flange splices. The horizontal force in the web shall be computed as the portion of the factored moment for checking slip at the point of splice that exceeds the moment resistance provided by the nominal slip resistance of the flange splice bolts divided by the appropriate moment arm determined as specified herein. The factored shear for checking slip shall be taken as the shear in the web at the point of splice under Load Combination Service II, as specified in Table 3.4.1-1, or the factored shear in the web at the point of splice due to the deck placement sequence as specified in Article 6.10.3.1, whichever governs.

For the box sections specified in Article 6.13.6.1.3b, the shear for checking slip shall be taken as the sum of the factored flexural and St. Venant torsional shears in the web subjected to additive shears. For boxes with inclined webs, the factored shear shall be taken as the component of the factored vertical shear in the plane of the web.

The computed web slip force shall be divided by the nominal slip resistance of the bolts, determined as specified in Article 6.13.2.8, to determine the total number of web splice bolts required on one side of the splice to resist slip.

Webs shall be spliced symmetrically by plates on each side. The splice plates shall extend as near as practical for the full depth between flanges without impinging on bolt assembly clearances or fillet areas on rolled beams. For bolted web splices with thickness differences of 0.0625 in. or less, filler plates should not be provided.

$$H_w = \frac{Web\ Moment}{A_w}$$

A_w is measured from the mid-depth of the web to the mid-thickness of the deck.

Figure C6.13.6.1.3c-1—Calculation of the Horizontal Force in the Web, H_w , for Composite Sections Subject to Positive Flexure

Figure C6.13.6.1.3c-2 illustrates the computation of the horizontal force in the web, H_w , where necessary for composite sections subject to negative flexure and noncomposite sections. The web moment is again taken as the portion of the factored moment that exceeds the moment resistance provided by the flanges. In this case, however, H_w is taken as the web moment divided by $D/4$, as shown in Figure C6.13.6.1.3c-2.

Figure C6.13.6.1.3c-2—Calculation of the Horizontal Force in the Web, H_w , for Composite Sections Subject to Negative Flexure and Noncomposite Sections

The required moment resistance in the web for the case shown in Figure C6.13.6.1.3c-1 is provided by a horizontal tensile force, H_w , assumed acting at the mid-depth of the web that is equilibrated by an equal and opposite horizontal compressive force in the concrete deck. The required moment resistance in the web for the case shown in Figure C6.13.6.1.3c-2 is provided by two equal and opposite horizontal tensile and compressive forces, $H_w/2$, assumed acting at a distance $D/4$ above and below the mid-height of the web. In each case, there is no net horizontal force acting on the section.

Because the resultant web force is assumed divided equally to all of the bolts, the traditional vector analysis is not applied.

In cases where the moment resistance provided by the flange splice bolts is sufficient at the strength limit state, but a moment contribution from the web is required to resist slip, the number of flange splice bolts may be increased to increase the moment resistance provided by the nominal slip resistance of the flange splice bolts. This can be done, if necessary, to prevent having to add an additional row of web splice bolts to resist the resultant web slip force.

Since slip is a serviceability requirement, the effect of the additional St. Venant torsional shear in the web is to be considered for the box sections specified in Article 6.13.6.1.3b when checking for slip.

When a moment contribution from the web is required at the strength limit state, the resultant forces causing bearing on the web bolt holes are inclined; that is, with a horizontal component of force equal to H_w divided by the number of web bolts and a vertical component of force equal to V_r divided by the number of web bolts. The bearing resistance of each bolt hole in the web can conservatively be calculated in this case using the clear edge distance, as shown on the left of Figure C6.13.6.1.3c-3. This calculation is conservative since the resultant forces act in the direction of inclined distances that are larger than the clear edge distance. This calculation is also likely to be a conservative calculation for the bolt holes in the adjacent rows. Should the bearing resistance be exceeded, it is recommended that the edge distance be increased slightly in lieu of increasing the number of bolts or thickening the web. Other options would be to calculate the bearing resistance based on the inclined distance or to resolve the resultant force in the direction parallel to the edge distance, or to refine the calculation for the bolt holes in the adjacent rows. In cases where the bearing resistance of the web splice plates controls, the smaller of the clear edge or end distance on the splice plates can be used to compute the bearing resistance of each hole as shown on the right of Figure C6.13.6.1.3c-3.

Figure C6.13.6.1.3c-3—Computing the Bearing Resistance of the Web Splice Bolt Holes for an Inclined Resultant Design Web Force

Required bolt assembly clearances are given in AISC (2023).

6.13.6.1.4—Fillers

When bolts carrying loads pass through fillers 0.25 in. or more in thickness in axially loaded connections, including girder flange splices, either:

- The fillers shall be extended beyond the gusset or splice material, and the filler extension shall be secured by enough additional bolts to distribute the total stress in the member uniformly over the combined section of the member and the filler or
- As an alternative, the fillers need not be extended and developed provided that the factored resistance of the bolts in shear at the strength limit state, specified in Article 6.13.2.2, is reduced by the following factor:

$$R = \left[\frac{(1 + \gamma)}{(1 + 2\gamma)} \right] \quad (6.13.6.1.4-1)$$

where:

- $\gamma = A_f/A_p$
- $A_f =$ sum of the area of the fillers on both sides of the connected plate (in.²)
- $A_p =$ smaller of either the connected plate area on the side of the connection with the filler or the sum of the splice plate areas on both sides of the connected plate (in.²); for truss gusset plate chord splices, when considering the gusset plate(s), only the portion of the gusset plate(s) that overlaps the connected plate shall be considered in the calculation of the splice plate areas

For slip-critical connections, the nominal slip resistance of a bolt, specified in Article 6.13.2.8, shall not be adjusted for the effect of the fillers.

Fillers 0.25 in. or more in thickness shall consist of not more than two plates, unless approved by the Engineer. The actual total filler thickness may exceed the

C6.13.6.1.4

Fillers are to be secured by means of additional fasteners so that the fillers are, in effect, an integral part of a shear-connected component at the strength limit state. The integral connection results in well-defined shear planes and no reduction in the factored shear resistance of the bolts.

In lieu of extending and developing the fillers, the reduction factor given by Eq. 6.13.6.1.4-1 may instead be applied to the factored resistance of the bolts in shear. This factor compensates for the reduction in the nominal shear resistance of a bolt caused by bending in the bolt and will typically result in the need to provide additional bolts in the connection. The reduction factor is only to be applied on the side of the connection with the fillers. The factor in Eq. 6.13.6.1.4-1 was developed mathematically (Sheikh-Ibrahim, 2002), and verified by comparison to the results from an experimental program on axially loaded bolted splice connections with undeveloped fillers (Yura, et al., 1982). The factor is more general than a similar factor given in AISC (2022b) in that it takes into account the areas of the main connected plate, splice plates and fillers and can be applied to fillers of any thickness. Unlike the empirical AISC factor, the factor given by Eq. 6.13.6.1.4-1 will typically be less than 1.0 for connections utilizing 0.25-in. thick fillers in order to ensure both adequate shear resistance and limited deformation of the connection.

For slip-critical connections, the nominal slip resistance of a bolt need not be adjusted for the effect of the fillers. The resistance to slip between filler and either connected part is comparable to that which would exist between the connected parts if fillers were not present.

A tolerance of up to 0.25 in. on the total filler thickness is permitted should fabrication or rolling tolerances require the use of an additional filler not shown in the contract documents in order to adequately mate the fillers with the outer surface of the flange on the other side of the splice. A reduction in the specified filler thickness is permitted without restriction. Test results (Frank and Yura, 1981) (Dusicka and Lewis, 2010) have shown that a 0.25-in-thick filler does not significantly reduce the resistance of the connection.

total filler thickness shown in the contract documents by up to a maximum of 0.25 in.

The specified minimum yield strength of fillers 0.25 in. or greater in thickness should not be less than the larger of 70 percent of the specified minimum yield strength of the connected plate and 36.0 ksi.

For fillers 0.25 in. or greater in thickness in axially loaded bolted connections, the specified minimum yield strength of the fillers should theoretically be greater than or equal to the specified minimum yield strength of the connected plate times the factor $[1/(1+\gamma)]$ in order to provide fully developed fillers that act integrally with the connected plate. However, such a requirement may not be practical or convenient due to material availability issues. As a result, premature yielding of the fillers, bolt bending and increased deformation of the connection may occur in some cases at the strength limit state. To control excessive deformation of the connection, a lower limit on the specified minimum yield strength of the filler plate material is recommended for fillers 0.25 in. or greater in thickness. Connections where the fillers are appropriately extended and developed or where additional bolts are provided according to Eq. 6.13.6.1.4-1 in lieu of extending the fillers, but that do not satisfy the recommended yield strength limit, will still have adequate reserve shear resistance in the connection bolts. However, such connections will have an increased probability of larger deformations at the strength limit state. For fillers less than 0.25 in. in thickness, the effects of yielding of the fillers and deformation of the connection are considered inconsequential. For applications involving the use of weathering steels, a weathering grade product should be specified for the filler plate material.

6.13.6.2—Welded Splices

Welded splice design and details shall conform to the requirements of the latest edition of AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code* and the following provisions specified herein.

Welded butt splices for tension, compression, and flexural members shall be designed using complete joint penetration groove welds. The use of splice plates should be avoided.

Welded field splices should be arranged to minimize overhead welding.

Material of different widths spliced by butt welds shall have symmetric transitions conforming to Figure 6.13.6.2-1. The type of transition selected shall be consistent with the detail categories of Table 6.6.1.2.3-1 for the groove-welded splice connection used in the design of the member. The contract documents shall specify that butt weld splices joining material of different thicknesses be ground to a uniform slope between the offset surfaces, including the weld, of not more than one in 2.5.

C6.13.6.2

Flange width transition details typically show the transition starting at the butt splice. Figure 6.13.6.2-1 shows a preferred detail where the splice is located a minimum of 3.0 in. from the transition for ease in fitting runoff tabs. Where possible, constant width flanges are preferred in a shipping piece.

Figure 6.13.6.2-1—Splice Details

6.13.7—Rigid-Frame Connections

6.13.7.1—General

All rigid-frame connections shall be designed to resist the moments, shear, and axial forces due to the factored loading at the strength limit state.

6.13.7.2—Webs

The thickness of an unstiffened beam web shall satisfy:

$$t_w \geq \sqrt{3} \left(\frac{M_c}{\phi_y F_y d_b d_c} \right) \quad (6.13.7.2-1)$$

where:

- F_y = specified minimum yield strength of the web (ksi)
- M_c = column moment due to the factored loadings (kip-in.)
- d_b = beam depth (in.)

C6.13.7.1

The provisions for rigid-frame connections are well documented in Chapter 8 of ASCE (1971).

The rigidity is essential to the continuity assumed as the basis for design.

C6.13.7.2

d_c = column depth (in.)
 ϕ_v = resistance factor for shear, as specified in Article 6.5.4.2

When the thickness of the connection web is less than that given in Eq. 6.13.7.2-1, the web shall be strengthened by diagonal stiffeners or by a reinforcing plate in contact with the web over the connection area.

At knee joints where the flanges of one member are rigidly framed into the flange of another member, stiffeners shall be provided on the web of the second member opposite the compression flange of the first member where:

$$t_w < \frac{A_f}{t_b + 5k} \quad (6.13.7.2-2)$$

and opposite the tension flange of the first member where:

$$t_c < 0.4 \sqrt{A_f} \quad (6.13.7.2-3)$$

where:

t_w = thickness of web to be stiffened (in.)
 k = distance from outer face of flange to toe of web fillet of member to be stiffened (in.)
 t_b = thickness of flange transmitting concentrated force (in.)
 t_c = thickness of flange of member to be stiffened (in.)
 A_f = area of flange transmitting concentrated load (in.²)

6.14—PROVISIONS FOR STRUCTURE TYPES

6.14.1—Through-Girder Spans

Where beams or girders comprise the main members of through-spans, such members shall be stiffened against lateral deformation by means of gusset plates or knee braces with solid webs connected to the stiffeners on the main members and the floorbeams. Design of gusset plates shall satisfy the requirements of Article 6.14.2.8.

6.14.2—Trusses

6.14.2.1—General

Trusses should have inclined end posts. Laterally unsupported hip joints shall be avoided.

Main trusses shall be spaced a sufficient distance apart, center-to-center, to prevent overturning.

Effective depths of the truss shall be assumed as follows:

- The distance between centers of gravity of bolted chords, and
- The distance between centers of pins.

The provision for checking the beam or connection web ensures adequate strength and stiffness of the steel frame connection.

In bridge structures, diagonal stiffeners of minimum thickness will provide sufficient stiffness. Alternately, web thickness may be increased in the connection region.

The provisions for investigating a member subjected to concentrated forces applied to its flange by the flanges of another member framing into it are intended to prevent crippling of the web and distortions of the flange. It is conservative to provide stiffeners of a thickness equal to that of the flanges of the other member.

C6.14.1

This requirement may be combined with other plate stiffening requirements.

6.14.2.2—Truss Members

Members shall be symmetrical about the central plane of the truss.

If the shape of the truss permits, compression chords shall be continuous.

If web members are subject to reversal of stress, their end connections shall not be pinned.

Counters should be avoided.

6.14.2.3—Secondary Stresses

The design and details shall be such that secondary stresses will be as small as practicable. Stresses due to the dead load moment of the member shall be considered, as shall those caused by eccentricity of joints or working lines. Secondary stresses due to truss distortion or floorbeam deflection need not be considered in any member whose width measured parallel to the plane of distortion is less than one-tenth of its length.

6.14.2.4—Diaphragms

Diaphragms in truss members shall be provided according to the requirements specified in Article 6.7.4.5.

6.14.2.5—Camber

The length of the truss members shall be adjusted such that the camber will be equal to or greater than the deflection produced by the dead load.

The gross area of each truss member shall be used in computing deflections of trusses. If perforated plates are used, the effective area of the perforated plate shall be the net volume between centers of perforations divided by the length from center-to-center of perforations.

Design requirements for perforated plates shall satisfy the requirements specified in Articles 6.8.5.2 and 6.9.4.3.2.

6.14.2.6—Working Lines and Gravity Axes

Main members shall be proportioned so that their gravity axes will be as nearly as practicable in the center of the section.

In compression members of an unsymmetrical section, such as chord sections formed of side segments and a cover plate, the gravity axis of the section shall

C6.14.2.2

Chord and web truss members should usually be made of H-shaped, channel-shaped, or box-shaped members. The member or component thereof may be a rolled shape or a fabricated shape using welding or mechanical fasteners. Side plates or components should be solid. Cover plates or web plates may be solid or perforated.

In chords composed of angles in channel-shaped members, the vertical legs of the angles preferably should extend downward.

Counters are sometimes used as web members of light trusses.

Counters should be rigid. If used, adjustable counters should have open turnbuckles, and in the design of these members an allowance of 10.0 ksi shall be made for initial stress. Only one set of diagonals in any panel should be adjustable. Sleeve nuts and loop bars should not be used. The load factor for initial stress should be taken as 1.0.

coincide as nearly as practicable with the working line, except that eccentricity may be introduced to counteract dead load flexure. In two-angle bottom chord or diagonal members, the working line may be taken as the gauge line nearest the back of the angle or at the center of gravity for welded trusses.

6.14.2.7—Portal and Sway Bracing

6.14.2.7.1—General

The need for vertical cross-frames used as sway bracing in trusses shall be investigated. Any consistent structural analysis with or without intermediate sway bracing shall be acceptable as long as equilibrium, compatibility, and stability are satisfied for all applicable limit states.

6.14.2.7.2—Through-Truss Spans

Through-truss spans shall have portal bracing or the strength and stiffness of the truss system shall be shown to be adequate without a braced portal. If portal bracing is used, it should be of the two-plane or box-type, rigidly connected to the end post and the top chord flanges, and be as deep as the clearance will allow. If a single-plane portal is used, it should be located in the central transverse plane of the end posts, with diaphragms between the webs of the posts to provide for a distribution of the portal stresses.

The portal, with or without bracing, shall be designed to take the full reaction of the top chord lateral system, and the end posts shall be designed to transfer this reaction to the truss bearings.

6.14.2.7.3—Deck Truss Spans

Deck truss spans shall have sway bracing in the plane of the end posts, or the strength and stiffeners of the truss system shall be shown to be adequate. Where sway bracing is used, it shall extend the full depth of the trusses below the floor system, and the end sway bracing shall be proportioned to carry the entire upper lateral load to the supports through the end posts of the truss.

6.14.2.8—Gusset Plates

6.14.2.8.1—General

Gusset or connection plates should be used for connecting truss members, except where the members are pin-connected. The fasteners connecting each member shall be symmetrical with the axis of the member, so far as practicable, and the connection of all the elements of the member should be given consideration to facilitate the load transfer.

Re-entrant cuts, except curves made for appearance, should be avoided as far as practicable.

C6.14.2.7.3

Generally, full depth sway bracing is easily accommodated in deck trusses, and its use is encouraged.

C6.14.2.8.1

The provisions provided in this Article are intended for the design of double gusset-plate connections used in trusses. The validity of the requirements for application to single gusset-plate connections has not been verified.

These provisions are based on the findings of NCHRP Project 12-84 (Ocel, 2013). Example calculations illustrating the application of the resistance equations for gusset-plate connections contained herein are provided in Ocel (2013).

Gusset plates shall satisfy the minimum plate thickness requirement for gusset plates used in trusses specified in Article 6.7.3. Gusset plates shall be designed for shear, compression, or tension occurring in the vicinity of each connected member, or some combination thereof, as applicable, according to the requirements specified in Articles 6.14.2.8.3 through 6.14.2.8.5. Gusset plates serving as a chord splice shall also be independently designed as a splice according to the provisions of Article 6.14.2.8.6. The edge slenderness requirement specified in Article 6.14.2.8.7 shall be considered.

Bolted gusset plate connections shall satisfy the applicable requirements of Articles 6.13.1 and 6.13.2. Where filler plates are required, the provisions of Article 6.13.6.1.4 shall apply.

6.14.2.8.2—Multilayered Gusset and Splice Plates

Where multilayered gusset and splice plates are used, the resistances of the individual plates may be added together when determining the factored resistances specified in Articles 6.14.2.8.3 through 6.14.2.8.6 provided that enough fasteners are present to develop the force in the layered gusset and splice plates.

6.14.2.8.3—Shear Resistance

The factored shear resistance of gusset plates, V_r , shall be taken as the smaller value based on shear yielding or shear rupture.

For shear yielding, the factored shear resistance shall be taken as:

$$V_r = \phi_{vy} 0.58 F_y A_{vg} \Omega \quad (6.14.2.8.3-1)$$

where:

- ϕ_{vy} = resistance factor for truss gusset plate shear yielding, specified in Article 6.5.4.2
- Ω = shear reduction factor for gusset plates, taken as 0.88
- A_{vg} = gross area of the shear plane (in.²)
- F_y = specified minimum yield strength of the gusset plate (ksi)

For shear rupture, the factored shear resistance shall be determined from Eq. 6.13.5.3-2.

Shear shall be checked on relevant partial and full failure plane widths. Partial shear planes shall only be checked around compression members and only Eq. 6.14.2.8.3-1 shall apply to partial shear planes. The partial shear plane length shall be taken along adjoining member fastener lines between plate edges and other fastener lines. The following partial shear planes, as

C6.14.2.8.2

Kulak et al. (1987) contains additional guidance on determining the number of fasteners required to develop the force in layered gusset and splice plates.

C6.14.2.8.3

The Ω shear reduction factor is used only in the evaluation of truss gusset plates for shear yielding. This factor accounts for the nonlinear distribution of shear stresses that form along a failure plane as compared to an idealized plastic shear stress distribution. The nonlinearity primarily develops due to shear loads not being uniformly distributed on the plane and also due to strain hardening and stability effects. The Ω -factor was developed using shear yield data generated in NCHRP Project 12-84 (Ocel, 2013). On average, Ω was 1.02 for a variety of gusset-plate geometries; however, there was significant scatter in the data due to proportioning of load between members, and variations in plate thickness and joint configuration. The specified Ω -factor has been calibrated to account for shear plane length-to-thickness ratios varying from 85 to 325.

Failure of a full width shear plane requires relative mobilization between two zones of the plate, typically along chords. Mobilization cannot occur when a shear plane passes through a continuous member; for instance, a plane passing through a continuous chord member that would require shearing of the member itself.

Research has shown that the buckling of connections with tightly spaced members is correlated with shear yielding around the compression members (Ocel, 2013). This is important because the buckling criteria used in Article 6.14.2.8.4 would overestimate the compressive buckling resistance of these types of connections. Once a plane yields in shear, the reduction in the plate modulus

applicable, shall be evaluated to determine which shear plane controls:

- The plane that parallels the chamfered end of the compression member, as shown in Figure 6.14.2.8.3-1;
- The plane on the side of the compression member that has the smaller framing angle between the member and the other adjoining members, as shown in Figure 6.14.2.8.3-2; and
- The plane with the least cross-sectional shear area if the member end is not chamfered and the framing angle is equal on both sides of the compression member.

Figure 6.14.2.8.3-1—Example of a Controlling Partial Shear Plane that Parallels the Chamfered End of the Compression Member Since that Member Frames In at an Angle of 45 Degrees to Both the Chord and the Vertical

Figure 6.14.2.8.3-2—Example of a Controlling Partial Shear Plane on the Side of a Compression Member Without a Chamfered End that has the Smaller Framing Angle between that Member and the Other Adjoining Members (i.e., $\theta < \alpha$)

reduces the out-of-plane stiffness such that the stability of the plate is affected. Generally, truss verticals and chord members are not subject to the partial plane shear yielding check because there is no adjoining member fastener line that can yield in shear and cause the compression member to become unstable. For example, the two compression members shown in Figure C6.14.2.8.3-1 would not be subject to a partial plane shear check.

Figure C6.14.2.8.3-1—Example Showing Truss Vertical and Chord Members in Compression that Do Not Require a Partial Shear Plane Check

6.14.2.8.4—Compressive Resistance

The factored compressive resistance, P_r , of gusset plates shall be taken as:

$$P_r = \phi_{cg} P_n \quad (6.14.2.8.4-1)$$

where:

- ϕ_{cg} = resistance factor for truss gusset plate compression specified in Article 6.5.4.2
 P_n = nominal compressive resistance of a Whitmore section determined from Eq. 6.9.4.1.1-1 or 6.9.4.1.1-2, as applicable (kip)

In the calculation of P_n , the elastic critical buckling resistance, P_e , shall be taken as:

$$P_e = \frac{3.29E}{\left(\frac{L_{mid}}{t_g}\right)^2} A_g \quad (6.14.2.8.4-2)$$

where:

- A_g = gross cross-sectional area of the Whitmore section determined based on 30 degree dispersion angles, as shown in Figure 6.14.2.8.4-1 (in.²), the Whitmore section shall not be reduced if the section intersects adjoining member bolt lines
 L_{mid} = distance from the middle of the Whitmore section to the nearest member fastener line in the direction of the member, as shown in Figure 6.14.2.8.4-1 (in.)
 t_g = gusset-plate thickness (in.)

Figure 6.14.2.8.4-1—Example Connection Showing the Whitmore Section for a Compression Member Derived from 30 Degree Dispersion Angles and the Distance, L_{mid}

C6.14.2.8.4

Gusset plate zones in the vicinity of compression members are to be designed for plate stability. Experimental testing and finite-element simulations performed as part of NCHRP Project 12-84 (Ocel, 2013) and by others (Yamamoto et al., 1988) (Higgins et al., 2013) have found that truss gusset plates subject to compression always buckle in a sidesway mode in which the end of the compression member framing into the gusset plate moves out-of-plane. The buckling resistance is dependent on the chamfering of the member, the framing angles of the members entering the gusset, and the standoff distance of the compression member relative to the surrounding members, i.e., the distance, L_{mid} . An example connection showing a typical chamfered member end and member framing angle is provided in Figure C6.14.2.8.4-1. The research found that the compressive resistance of gusset plates with large L_{mid} distances was reasonably predicted using modified column buckling equations and Whitmore section analysis. When the members were heavily chamfered reducing the L_{mid} distance, the buckling of the plate was initiated by shear yielding on the partial shear plane adjoining the compression member causing a destabilizing effect, as discussed in Article C6.14.2.8.3.

Eq. 6.14.2.8.4-2 is derived by substituting plate properties into Eq. 6.9.4.1.2-1 along with an effective length factor of 0.5 that was found to be relevant for a wide variety of gusset plate geometries (Ocel, 2013).

Figure C6.14.2.8.4-1—Example Connection Showing a Typical Chamfered Member End and Member Framing Angle

The provisions of this Article shall not be applied to compression chord splices.

6.14.2.8.5—Tensile Resistance

The factored tensile resistance, R_t , of gusset plates shall be taken as the smallest factored resistance in tension based on yielding, fracture, or block shear rupture determined according to the provisions of Article 6.13.5.2. When checking Eqs. 6.8.2.1-1 and 6.8.2.1-2, the Whitmore section defined in Figure 6.14.2.8.5-1 shall be used to define the effective area. The Whitmore section shall not be reduced if the width intersects adjoining member bolt lines.

Figure 6.14.2.8.5-1—Example Connection Showing the Whitmore Section for a Tension Member Derived from 30 Degree Dispersion Angles

The provisions of this Article shall not be applied to tension chord splices.

6.14.2.8.6—Chord Splices

Gusset plates that splice two chord sections together shall be checked using a section analysis considering the relative eccentricities between all plates crossing the splice and the loads on the spliced plane.

For compression chord splices, the factored compressive resistance, P_r , of the spliced section shall be taken as:

$$P_r = \phi_{cs} F_{cr} \left(\frac{S_g A_g}{S_g + e_p A_g} \right) \quad (6.14.2.8.6-1)$$

in which:

F_{cr} = stress in the spliced section at the limit of usable resistance (ksi). F_{cr} shall be taken as the specified minimum yield strength of the gusset plate when the following equation is satisfied:

C6.14.2.8.6

This Article is not intended to cover the design of chord splices that occur outside of the gusset plates; this situation is covered by the provisions of Article 6.13.6.1.1 or 6.13.6.1.2, as applicable. For gusset plates also serving the role of a chord splice, the forces from all members framing into the connection must be considered. The chord splice forces are the resolved axial forces acting on each side of the spliced section, as illustrated in Figure C6.14.2.8.6-1. Generally, a difference in the resolved forces on the two sides of a chord splice arises due to the use of envelope forces, i.e., forces due to noncurrent loads. Where envelope forces are used, the resolved forces should include consideration of the concurrence or nonconcurrence of forces to avoid potentially unconservative reductions in the connection force. The chord splice should be investigated for the larger of the two resolved forces on either side of the splice.

For chord splices that are in full compression under the loads being considered and that are detailed with

$$\frac{KL_{splice}\sqrt{12}}{t_g} < 25 \quad (6.14.2.8.6-2)$$

where:

- ϕ_{cs} = resistance factor for truss gusset plate chord splices, specified in Article 6.5.4.2
- A_g = gross area of all plates in the cross-section intersecting the spliced plane (in.²)
- e_p = distance between the centroid of the cross-section and the resultant force perpendicular to the spliced plane (in.)
- K = effective column length factor taken as 0.50 for chord splices
- L_{splice} = center-to-center distance between the first lines of fasteners in the adjoining chords as shown in Figure 6.14.2.8.6-1 (in.)
- S_g = gross section modulus of all plates in the cross-section intersecting the spliced plane (in.³)
- t_g = gusset plate thickness (in.)

Figure 6.14.2.8.6-1—Example Connection Showing Chord Splice Parameter, L_{splice}

milled ends in full contact bearing at the splice, resolved forces may be adjusted to account for the transfer of a portion of the compressive load through end bearing as long as the capacity in bearing is verified. The portion of the compressive load that may be transferred in bearing in such cases is specified in Article 6.13.6.1.2.

Figure C6.14.2.8.6-1—Example Connection Showing the Resolution of the Member Forces into Forces Acting on Each Side of a Chord Splice

The resistance equations in this Article assume the gusset and splice plates behave as one combined spliced section to resist the applied axial load and eccentric bending that occur due to the fact that the resultant forces on the section are offset from the centroid of the combined section, as illustrated in Figure C6.14.2.8.6-2. The combined spliced section is treated as a beam and the factored resistance at the strength limit state is determined assuming the stress in the combined section at the limit of usable resistance is equal to the specified minimum yield strength of the gusset plate if the slenderness limit for the spliced section given by Eq. 6.14.2.8.6-2 is met, which will typically be the case. If not, the Engineer will need to derive a reduced value of F_{cr} to account for possible elastic buckling of the gusset plate within the splice.

Figure C6.14.2.8.6-2—Illustration of the Combined Spliced Section at a Chord Splice

For tension chord splices, the factored tensile resistance, P_r , shall be taken as the lesser of the values given by Eqs. 6.14.2.8.6-3 and 6.14.2.8.6-4.

$$P_r = \phi_{cs} F_y \left(\frac{S_g A_g}{S_g + e_p A_g} \right) \quad (6.14.2.8.6-3)$$

$$P_r = \phi_{cs} F_u \left(\frac{S_n A_n}{S_n + e_p A_n} \right) \quad (6.14.2.8.6-4)$$

where:

- ϕ_{cs} = resistance factor for truss gusset plate chord splices, specified in Article 6.5.4.2
- A_g = gross area of all plates in the cross-section intersecting the spliced plane (in.²)
- A_n = net area of all plates in the cross-section intersecting the spliced plane (in.²)
- e_p = distance between the centroid of the cross-section and the resultant force perpendicular to the spliced plane (in.)
- F_y = specified minimum yield strength of the gusset plate (ksi)
- F_u = specified minimum tensile strength of the gusset plate (ksi)
- S_g = gross section modulus of all plates in the cross-section intersecting the spliced plane (in.³)
- S_n = net section modulus of all plates in the cross-section intersecting the spliced plane (in.³)

Tension chord splice members shall also be checked for block shear rupture as specified in Article 6.13.4.

6.14.2.8.7—Edge Slenderness

If the length of the unsupported edge of a gusset plate exceeds $2.06t_g(E/F_y)^{1/2}$, where t_g is the gusset plate thickness and F_y is the specified minimum yield strength of the gusset plate, the edge should be stiffened.

6.14.2.9—Half Through-Trusses

The vertical truss members and the floorbeams and their connections in half through-truss spans shall be proportioned to resist a lateral force of not less than 0.30 klf applied at the top chord panel points of each truss, considered as a permanent load for the Strength I Load Combination and factored accordingly.

The Whitmore section check specified in Article 6.14.2.8.4 is not considered applicable for the design of a compression chord splice.

The yielding and net section fracture checks on the Whitmore section specified in Article 6.14.2.8.5 are not considered applicable for the design of a tension chord splice.

C6.14.2.8.7

This Article is intended to provide good detailing practice to reduce deformations of free edges during fabrication, erection, and service versus providing an increase in the member compressive buckling resistance at the strength limit state. NCHRP Project 12-84 (Ocel, 2013) found no direct correlation between the buckling resistance of the gusset plate and the free edge slenderness. There are no criteria specified for sizing of the edge stiffeners but the traditional practice of using angles with leg thicknesses of 0.50 in. has generally provided adequate performance.

C6.14.2.9

The top chord shall be considered as a column with elastic lateral supports at the panel points.

6.14.2.10—Factored Resistance

The factored resistance of tension members shall satisfy the requirements specified in Article 6.8.2.

The factored resistance of compression members shall satisfy the requirements specified in Article 6.9.2.

The nominal bending resistance of the members whose factored resistance is governed by interaction equations, specified in Articles 6.8.2.3 or 6.9.2.2, shall be evaluated as specified in Article 6.12.

6.14.3—Orthotropic Deck Superstructures

6.14.3.1—General

The provisions of this Article shall apply to the design of steel bridges that utilize a stiffened steel plate as a deck. An orthotropic deck shall be considered an integral part of the bridge superstructure and shall participate in resisting global force effects on the bridge. Connections between the deck and the main structural members shall be designed for interaction effects specified in Article 9.4.1.

The combined effects of global and local forces shall be considered when analyzing the orthotropic deck. The effect of torsional distortions of the cross-sectional shape shall be accounted for in analyzing the deck plate and girders of orthotropic box girder bridges.

6.14.3.2—Decks in Global Compression

6.14.3.2.1—General

The following potential stability-related behaviors shall be evaluated in the orthotropic plate: local buckling of the deck plate between ribs, local buckling of the rib wall, and buckling of the orthotropic panel between floorbeams.

6.14.3.2.2—Local Buckling

For local buckling, the slenderness of each component shall be considered: the rib spacing to deck thickness ratio, the closure spacing to deck thickness ratio (for closed ribs), and the rib height to rib thickness ratio for the ribs. The effective width for each component shall be determined in accordance with Article 6.9.4.2.

A discussion of the buckling analysis of columns with elastic lateral supports is contained in Timoshenko and Gere (1961) and in Ziemian (2010).

C6.14.3.1

Orthotropic deck roadways may be used as upper or lower flanges of trusses, plate-girder or box-girder bridges, stiffening members of suspension or cable-stayed bridges, tension ties of arch bridges, etc.

Detailed provisions for the design of orthotropic decks are given in Article 9.8.3.

C6.14.3.2.2

Article 6.9.4 applies the recommended method for quantification of strength reduction resulting from local buckling, as given by *Specification for Structural Steel Buildings* for slender element cross-sections (AISC, 2022b). This unified effective width method is based on Peköz (1986) and is also the basis of *North American Specification for the Design of Cold-Formed Steel Structural Members* (AISI, 2016).

For local buckling considerations, the deck plate and the rib walls can be considered to be plates supported along two longitudinal edges.

6.14.3.2.3—Panel Buckling

C6.14.3.2.3

Each panel between floorbeams may be simplified for analysis as an isolated strut comprised of the rib and effective deck width specified in Figure 6.14.3.2.3-1.

In-plane compressive resistance is controlled by stability. Buckling behavior of stiffened plate panels is a complicated problem due to the two-way orthogonal stiffening behavior and partially restrained boundary supports on four sides of the panel. A summary of relevant historical research on this subject is provided in Troitsky (1977) and Ziemian (2010). Similar to stiffened plate elements, reserve post-buckling strength in the panel exists beyond the point of initial buckling and can be quantified by use of the local effective width approach.

A simplified approach to estimating the buckling strength of the stiffened panel is to analyze the panel as a series of isolated column struts comprised of a stiffener and the associated effective width of plating (Home and Narayanan, 1977). Then, basic column theory can be employed. This approach conservatively neglects the bending and membrane stiffness of the panel in the transverse direction and the torsional stiffness of the closed rib sections. Alternately, refined analysis may be used for a more accurate assessment of panel buckling strength with full consideration of the orthogonal stiffening behavior.

Figure 6.14.3.2.3-1—Idealized Strut for Evaluation of Compressive Resistance

where:

- a = the width of the closed rib at the deck plate, centerline rib plate to centerline rib plate (in.)
- e = the clear spacing between adjacent ribs, centerline rib plate to centerline rib plate (in.)

The critical buckling stress of the strut shall be determined in accordance with Article 6.9.4 or by methods of refined analysis as defined in Article 4.6.3.2.3.

6.14.3.3—Effective Width of Deck

The provisions of Article 4.6.2.6.4 shall apply.

6.14.3.4—Superposition of Global and Local Effects

In calculating extreme force effects in the deck, global and local effects shall be superimposed. Such combined force effects shall be computed for the same configuration and position of live load.

6.14.4—Solid Web Arches**6.14.4.1—General**

These provisions are applicable for arch ribs satisfying the following limits:

- For flange extensions of box sections, flanges of I-sections, and/or web longitudinal stiffeners:

$$\frac{b}{t} \leq 0.12 \frac{R}{b} \quad (6.14.4.1-1)$$

- For flanges of box sections:

$$\frac{b_{fi}}{t} \leq 0.47 \frac{R}{b_{fi}} \quad (6.14.4.1-2)$$

where:

R = radius of curvature of the arch rib at the mid-depth of the web for the section under consideration (in.)

b_{fi} = clear width of the flange under consideration between the insides of the webs (in.)

b = unsupported width of the cross-section plate component under consideration (in.) taken as follows:

- For flange extensions of box sections:

= clear projecting width of the flange under consideration measured from the outside surface of the web (in.)

- For I-section flanges:

= one-half the total width of the flange (in.)

- For web longitudinal stiffeners:

= projecting width of the longitudinal stiffener relative to the surface of the web (in.)

t = thickness of the cross-section plate component under consideration (in.)

Where longitudinal stiffeners are employed on flanges of arch ribs, transfer of the radial load from the axial force in the longitudinal stiffeners acting through the vertical curve to the webs of the arch rib shall be considered.

C6.14.4.1

The restrictions on arch rib proportions specified in this Article eliminate the need for the consideration of any reduction on the strength of arch rib plate elements due to the influence of the vertical curvature of the arch rib. The geometry of most arch ribs is such that no reduction is required for the influence of the vertical curvature on the strength of the flange plates and the web stiffener plates. White et al. (2019b) provide equations for a reduction in the effective yield strength of the arch rib component plates that extends the provisions of Article 6.14.4 to a broader range of geometries.

The use of longitudinal stiffeners on arch rib flanges is discouraged. The action of the axial force in flange longitudinal stiffeners acting through the vertical curvature of the arch rib induces significant radial forces from the longitudinal stiffeners, which must be transferred to the web or webs of the arch rib. In addition, for other than potentially free-standing arches, it is unlikely that the flanges of arch ribs would need to be wide enough to benefit from longitudinal stiffening of the flanges.

For unusual cases where the flanges in box-section arch ribs have longitudinal stiffeners, the radial load from the axial force in the longitudinal stiffeners acting through the vertical curve must be transferred from the

Web longitudinal stiffeners on arch ribs should be flat plates and shall satisfy the requirements of Article E6.1.3.

If the requirements of Article 6.10.11.3 are not satisfied for longitudinally stiffened webs, the member flexural resistance should be calculated neglecting the longitudinal stiffeners when determining R_b in Article 6.10.1.10.2.

6.14.4.2—Web Slenderness

The web or webs of arch ribs shall satisfy the following in addition to the applicable web slenderness requirements from Articles 6.10.2.1 or 6.12.2.2.2b:

$$\frac{d_{fs}}{t_w} \leq \frac{0.40 \frac{E}{F_{yf}}}{\sqrt{1 + \frac{0.18}{(R/D)} \frac{E}{F_{yf}}}} \quad (6.14.4.2-1)$$

where:

- d_{fs} = web depth for ribs with webs that are longitudinally unstiffened; maximum distance between the compression or the tension flange and the adjacent longitudinal stiffener for ribs with webs that are longitudinally stiffened (in.)
- D = web depth (in.)
- F_{yf} = specified minimum yield strength of the flange under consideration (ksi)
- R = radius of curvature of the arch rib at the mid-depth of the web for the section under consideration (in.)
- t_w = web thickness (in.)

6.14.4.3—Moment Amplification

For moment amplification, the provisions specified in Article 4.5.3.2.2c shall be satisfied.

longitudinal stiffeners to the webs of the arch rib, or longitudinally to transverse stiffening elements and then to the webs of the arch rib. For flanges with only one longitudinal stiffener and a wide spacing of transverse stiffeners and diaphragms, the likely predominant load path for this force transfer is via transverse bending of the flange plate. White et al. (2019b) provide further discussion of this consideration.

Tee or angle-section stiffeners on the webs of arch ribs also tend to exhibit significant bending in the direction normal to the stem or leg attached to the web, due to the axial force in the stiffener acting through the vertical curvature of the arch rib. This tends to cause twisting of the stiffener about the location of its connection to the stiffened plate, which exacerbates the behavior associated with the tripping limit state of the stiffener discussed in Article CE6.1.3.

C6.14.4.2

Eq. 6.14.4.2-1 is a not-to-exceed limit that ensures the web or webs of arch ribs are sufficiently stout such that they are capable of resisting transverse compression forces developed by the flanges acting through the vertical curve of the arch rib. This equation is adapted from the Eurocode Part 1-5 (CEN, 2006) and AISC (2022b) equations for the limit state of “flange induced buckling,” traditionally referred to in American structural engineering practice as flange vertical buckling. Eq. 6.14.4.2-1 reduces to the corresponding equation in AISC (2022b) in the limit that the radius of curvature of the arch rib, R , approaches infinity; this equation addresses the impact of the initial vertical curvature of the rib, in addition to the curvature due to bending, via the ratio R/D .

6.14.4.4—Nominal Compressive Resistance

The nominal compressive resistance of noncomposite arch ribs shall be determined using the provisions specified in Article 6.9.4.1.

In lieu of a more rigorous buckling analysis, the in-plane elastic critical flexural buckling resistance of arch ribs shall be calculated using the K values specified in Table 4.5.3.2.2c-1.

In lieu of a more rigorous buckling analysis, the out-of-plane elastic critical flexural buckling resistance shall be calculated as specified in Article 4.6.2.5. The characteristics of the framing in the out-of-plane direction shall be considered in determining the out-of-plane elastic critical buckling resistance using either approach.

6.14.4.5—Nominal Flexural Resistance

The nominal flexural resistance of noncomposite arch ribs shall be determined using the provisions of Article 6.10 or 6.12, as applicable. The developed unbraced length along the vertical curve between the brace points, L_{db} , shall be used for the unbraced length L_b . The reduction of the LTB resistance due to the vertical curvature of the arch rib shall be considered. For box-section arch ribs with L_{db}/R greater than 0.20, subjected to bending moments causing compression on the flange farthest from the center of curvature of the rib, where R is the minimum radius of curvature of the arch rib measured to the mid-depth of the web, the moment-gradient modifier, C_b , may be multiplied by 0.90 in lieu of a more refined buckling analysis.

C6.14.4.5

For unbraced lengths in vertically curved members such as arch ribs, the LTB resistance of the member is reduced by the influence of the vertical curvature when the unbraced length is subjected to moments causing compression on the flange farthest from the center of curvature; that is, moments that tend to “straighten” the arch. The LTB resistance is increased by moments causing compression on the flange closest to the center of curvature; that is, moments that tend to increase the curvature of the arch. Increases in the LTB resistance due to these effects should be neglected. For typical unbraced lengths of box-section arch ribs with L_{db}/R greater than 0.20, subjected to moments that would reduce the LTB resistance, 0.90 is a reasonable lower-bound on the reduction in the elastic LTB resistance. This reduction may be applied conservatively to the C_b modifier. The adjustment to the C_b modifier for arch ribs composed of doubly symmetric open or closed sections may be determined more rigorously by a set of closed-form equations provided by Dowswell (2018). For arch ribs composed of singly symmetric open or closed sections, the adjustment to the C_b modifier may be determined by solving equations provided by Trahair and Papangelis (1987).

6.14.4.6—Combined Axial Compression or Tension with Flexure and Torsion

The interaction between axial compression or tension resistances, flexural resistances, and flexural shear and/or torsion shall be considered as specified in Articles 6.9.2.2 and 6.8.2.3, as applicable.

6.15—PILES**6.15.1—General**

Piles shall be designed as structural members capable of safely supporting all imposed loads.

For a pile group composed of only vertical piles which is subjected to lateral load, the pile structural

C6.15.1

Typically, due to the lack of a detailed soil–structure interaction analysis of pile groups containing both vertical and battered piles, evaluation of combined axial

analysis shall include explicit consideration of soil–structure interaction effects as specified in Article 10.7.3.9.

6.15.2—Structural Resistance

Resistance factors, ϕ_c and ϕ_f , for the strength limit state shall be taken as specified in Article 6.5.4.2. The resistance factors for axial resistance of piles in compression which are subject to damage due to driving shall be applied only to that section of the pile likely to experience damage. Therefore, the specified ϕ_c factors for axial resistance of 0.50 to 0.70 for piles in compression without bending shall be applied only to the axial capacity of the pile. The ϕ_c factors of 0.70 and 0.80 and the ϕ_f factor of 1.00 shall be applied to the combined axial and flexural resistance of the pile in the interaction equation for the compression and flexure terms, respectively.

and flexural loading will only be applied to pile groups containing all vertical piles.

C6.15.2

Due to the nature of pile driving, additional factors must be considered in selection of resistance factors that are not normally accounted for in steel members. The factors considered in development of the specified resistance factors include:

- Unintended eccentricity of applied load about pile axis,
- Variations in material properties of pile, and
- Pile damage due to driving.

These factors are discussed by Davisson et al. (1983). While the resistance factors specified herein generally conform to the recommendations given by Davisson et al. (1983), they have been modified to reflect current design philosophy.

The factored compressive resistance, P_r , includes reduction factors for unintended load eccentricity and material property variations as well as a reduction for potential damage to piles due to driving, which is most likely to occur near the tip of the pile. The resistance factors for computation of the factored axial pile capacity near the tip of the pile are 0.50 to 0.60 and 0.60 to 0.70 for severe and good driving conditions, respectively. These factors include a base axial compression resistance factor ϕ_c equal to 0.90, modified by reduction multipliers of 0.78 and 0.87 for eccentric loading of H-piles and pipe piles, respectively, and reduction multipliers of 0.75 and 0.875 for difficult and moderately difficult driving conditions.

For steel piles, flexure occurs primarily toward the head of the pile. This upper zone of the pile is less likely to experience damage due to driving. Therefore, relative to combined axial compression and flexure, the resistance factor for axial resistance range of $\phi_c = 0.70$ to 0.80 accounts for both unintended load eccentricity and pile material property variations, whereas the resistance factor for flexural resistance of $\phi_f = 1.00$ accounts only for base flexural resistance. This design approach is illustrated on Figure C6.15.2-1 which illustrates the depth to fixity as determined by P - Δ analysis.

provisions in Article 6.9 for compression members using an equivalent length of the pile equal to the laterally unsupported length, plus an embedded depth to fixity. The depth to fixity shall be determined in accordance with Article 10.7.3.13.4 for battered piles or P - Δ analysis for vertical piles.

6.15.4—Maximum Permissible Driving Stresses

Maximum permissible driving stresses for top driven steel piles shall be taken as specified in Article 10.7.8.

6.16—PROVISIONS FOR SEISMIC DESIGN

6.16.1—General

The provisions of Article 6.16 shall apply only to the design of slab-on-steel-girder bridge superstructures at the extreme event limit state.

In addition to the requirements specified herein, minimum support length requirements specified in Article 4.7.4.4 shall also apply.

A clear seismic load path shall be established within the superstructure to transmit the inertia forces to the substructure based on the stiffness characteristics of the concrete deck, cross-frames or diaphragms, and bearings. The flow of the seismic forces shall be accommodated through all affected components and connections of the steel superstructure within the prescribed load path, including, but not limited to, the longitudinal girders, cross-frames or diaphragms, steel-to-steel connections, deck-to-steel interface, bearings, and anchor rods.

C6.16.1

These Specifications are based on the work published by Itani et al. (2010), NCHRP (2002, 2006), MCEER/ATC (2003), Caltrans (2006), the AASHTO *Guide Specifications for LRFD Seismic Bridge Design*, and AISC (2022a and 2022b). The Loma Prieta earthquake of 1989, Petrolia earthquakes of 1992, Northridge earthquake of 1994, and the Hyogoken-Nanbu (Kobe) earthquake of 1995 provided new insights into the behavior of steel details under seismic loads. The Federal Highway Administration, Caltrans, and the American Iron and Steel Institute initiated a number of research projects that have produced information that is useful for both the design of new steel-girder structures and the retrofitting of existing steel-girder structures.

This new information relates to all facets of seismic engineering, including design spectra, analytical techniques, and design details. Bridge designers working in Seismic Zones 2, 3, or 4 are encouraged to avail themselves of current research reports and other literature to augment these Specifications.

Steel-girder bridges are generally considered to perform well in earthquakes. However, the aforementioned earthquakes showed the vulnerability of steel-girder bridges to damage if they are not designed and detailed to resist the seismic motions (Roberts, 1992) (Astaneh-Asl et al., 1994) (Itani and Reno, 1995) (Bruneau et al., 1996) (Carden et al., 2005a). Typical damage included unseated longitudinal girders and failure of cross-frames and their connections, expansion joints, and bearings. In a few cases, most notably during the Kobe earthquake, major gravity load-carrying members failed, triggered in some instances by the failure of components elsewhere in the superstructure. These earthquakes confirmed the vulnerability of steel-girder bridges during seismic events. New areas of concern that emerged included:

- Lack of understanding of the seismic load paths in steel-girder bridges;
- Damage to steel superstructure components, e.g., girders, shear connectors, end cross-frames,

bearing stiffeners, bearings, and anchor rods; and

- Failure of steel substructures.

Seismic design specifications in the U.S. currently do not require the explicit design of bridge superstructures for seismic loads. The assumption is made that a superstructure that is designed for out-of-plane gravity load has sufficient strength, by default, to resist in-plane seismic loads. However, recent earthquakes have shown the fallacy of this assumption and have shown that a load path should be clearly defined, analyzed, and designed for seismic loads.

Research on the seismic behavior of steel-girder bridge superstructures (Astaneh-Asl and Donikian, 1995) (Itani, 1995) (Diceli and Bruneau; 1995a, 1995b) (Itani and Rimal, 1996) (Carden et al.; 2005a, 2005b) (Bahrami et al., 2010) further confirmed that seismically induced damage is likely in superstructures subjected to large earthquakes and that appropriate measures should be taken to ensure satisfactory seismic performance.

The Kobe earthquake demonstrated the potential vulnerability of nonductile steel substructures. However, given that steel substructures are less commonly used in North America and are not of a standardized type when used, they are not addressed herein. The Engineer may find information on this topic in the *AASHTO Guide Specifications for LRFD Seismic Bridge Design* and MCEER/ATC (2003) to complement information available elsewhere in the literature.

These specifications concentrate on the seismic design and detailing of steel-girder bridge superstructures. These types of superstructures have experienced moderate earthquakes and have been investigated analytically and experimentally in the aforementioned research. The common thread among these investigations was that these types of superstructures are vulnerable during earthquakes if they are not designed and detailed to resist the resulting seismic forces. A continuous and clearly defined load path is necessary for the transmission of the superstructure inertia forces to the substructure.

6.16.2—Materials

Structural steels used within the seismic load path shall meet the requirements of Article 6.4.1, except as modified herein.

When a member or connection is protected by capacity design, the required nominal resistance of the member or connection shall be determined based on the expected yield strength, $R_y F_y$, of the adjoining member(s), where F_y is the specified minimum yield strength of the steel used in the adjoining member(s) and R_y is the ratio of the expected yield strength to the specified minimum yield strength. For AASHTO M 270M/M 270 (ASTM A709/A709M) Grade 36, R_y shall be taken equal to 1.5 for hot-rolled structural shapes and

C6.16.2

Previous earthquakes have shown that cross-frames at support locations transfer the inertia forces of the superstructure to the substructure. Therefore, the connections of the adjoining cross-frame members must be protected during seismic events. This is achieved by utilizing a capacity-design methodology in which the cross-frame connections are designed based on the expected nominal resistance of the adjoining members. This methodology serves to confine the ductility demand to the members that have the available excess resistance to ensure ductile behavior. In the capacity-design methodology, all the components surrounding the nonlinear element are designed based on the maximum

1.3 for plates. For AASHTO M 270M/M 270 (ASTM A709/A709M) Grades 50, 50S and 50W, R_y shall be taken equal to 1.1.

6.16.3—Design Requirements for Seismic Zone 1

For steel-girder bridges located in Seismic Zone 1, defined as specified in Article 3.10.6, the design of all support cross-frame or diaphragm members and their connections and the connections of the superstructure to the substructure shall satisfy the minimum requirements specified in Articles 3.10.9 and 4.7.4.4.

6.16.4—Design Requirements for Seismic Zones 2, 3, or 4

6.16.4.1—General

Components of slab-on-steel-girder bridges located in Seismic Zones 3 or 4, defined as specified in Article 3.10.6, shall be designed using one of the two types of response strategies specified in this Article. One of the two types of response strategies should be considered for bridges located in Seismic Zone 2:

- *Type A*—Design an elastic superstructure with a ductile substructure according to these Specifications.
- *Type B*—With the approval of the Owner including the design methodology, design an elastic superstructure and substructure with a fusing mechanism at the interface between the superstructure and substructure.

The deck and shear connectors on bridges located in Seismic Zones 3 or 4 shall also satisfy the provisions of Articles 6.16.4.2 and 6.16.4.3, respectively. If Strategy Types A or B are invoked for bridges in Seismic Zone 2, the provisions of Articles 6.16.4.2 and 6.16.4.3 should be considered.

Support cross-frame members on bridges located in Seismic Zones 3 or 4 shall be considered primary members for seismic design. Structural analysis for seismic loads shall consider the relative stiffness of the concrete deck, girders, support cross-frames or diaphragms, and the substructure.

expected nominal resistance of that element. The capacity-design methodology requires a realistic estimate of the expected nominal resistance of the designated yielded members. To this end, the expected yield strength of various steel materials has been established through a survey of mill test reports and ratios of the expected to nominal yield strength, R_y , have been provided elsewhere (AISC, 2022a) and they are adopted herein. The expected resistance of the designated member is therefore to be determined based on the expected yield strength, $R_y F_y$, which amplifies the nominal resistance to account for the effect of strain-hardening if the member is expected to undergo nonlinear response.

C6.16.3

These requirements for Zone 1 are to ensure a clear load path for seismic forces.

C6.16.4.1

The conventional seismic design strategy for slab-on-steel-girder bridges, denoted herein as Type A, is to provide an elastic superstructure in combination with a ductile substructure. In such cases, the support cross-frames are designed to transfer the seismic forces elastically and the inelasticity is limited to the concrete substructure, which is typically designed according to the provisions of Article 5.11. As used in this Article, an elastic component is one in which the demand-to-nominal resistance ratio is less than 1.0.

Providing an essentially elastic superstructure and substructure by utilizing response modification devices such as seismic isolation as a fusing mechanism is a viable alternative strategy to Type A for designing steel-girder bridges to resist earthquake loading. When seismic isolation is used, the Engineer is referred to the AASHTO *Guide Specifications for Seismic Isolation Design* (2014).

The provision of an alternative fusing mechanism between the interface of the superstructure and substructure by shearing off the anchor rods may also comprise an adequate seismic strategy. However, care must be taken to provide adequate support length and to stiffen the girder webs against out-of-plane forces at support locations. It is also anticipated that large deformations will occur in the superstructure at support locations during a seismic event where this strategy is employed.

The recommended design provisions for bridges located in Seismic Zone 2 have been included in this Article with the requirements for bridges located in Seismic Zones 3 and 4. Bridges located in Seismic Zone

6.16.4.2—Deck

Reinforced concrete decks attached by shear connectors satisfying the requirements of Article 6.16.4.3 shall be designed to provide horizontal diaphragm action to transfer seismic forces to the supports as specified in this Article.

Where the deck has a span-to-width ratio of 3.0 or less and the net midspan lateral seismic displacement of the superstructure is less than twice the average of the adjacent lateral seismic support displacements, the deck within that span may be assumed to act as a rigid horizontal diaphragm designed to resist only the shear resulting from the seismic forces. Otherwise, the deck shall be assumed to act as a flexible horizontal diaphragm designed to resist shear and bending, as applicable, resulting from the seismic forces.

The transverse seismic shear force on the deck, F_{px} , within the span under consideration shall be determined as:

$$F_{px} = \frac{W_{px}}{W} F \quad (6.16.4.2-1)$$

where:

F = force (kip) determined as follows:

- For structures in Seismic Zone 2 designed using Strategy Type A, the elastic transverse base shears at the support under consideration divided by a response modification factor, R , equal to 1.0.
- For structures in Seismic Zones 3 or 4 designed using Strategy Type A, the lesser of:
 - The elastic transverse base shears at the support under consideration divided by a response modification factor, R , equal to 1.0, and
 - The inelastic hinging force, determined as specified in Article 3.10.9.4.3.
- For structures in Seismic Zones 2, 3, or 4 designed using Strategy Type B, the expected lateral resistance of the fusing mechanism multiplied by an appropriate overstrength factor.

2 have a reasonable probability of being subjected to significant seismic forces because the upper boundary for this zone in the current edition of the specifications is significantly higher than in previous editions due to the increase in the return period for the design earthquake from 500 to 1,000 years.

In horizontally curved or skewed steel bridges, or both, cross-frame forces due to gravity loads may govern over seismic loads depending on boundary conditions at abutments; pier flexibility; and degree of curvature or skew, or both.

C6.16.4.2

In general, reinforced concrete decks on steel-girder bridges with adequate stud connectors have sufficient rigidity in their horizontal plane that their response approaches rigid-body motion. Therefore, the deck can provide a horizontal diaphragm action to transfer seismic forces to support cross-frames or diaphragms. The seismic forces are collected at the support cross-frames or diaphragms and transferred to the substructure through the bearings and anchor rods. Thus, the support cross-frames or diaphragms must be designed for the resulting seismic forces. The lateral loading of the intermediate cross-frames in-between the support locations for straight bridges is minimal in this case, consisting primarily of the local tributary inertia forces from the girders. Adequate stud connectors are required to ensure the necessary diaphragm action as previous earthquake reconnaissance showed that for some bridges in California in which the shear connectors at support locations were damaged during a seismic event, the deck in fact slid on the top of the steel girders (Roberts, 1992) (Carden et al., 2005a).

During a seismic event, inertia forces generated by the mass of the deck must be transferred to the support cross-frames or diaphragms. The seismic forces are transferred through longitudinal and transverse shear forces and axial forces.

In cases where the deck may be idealized as a rigid horizontal diaphragm, F_{px} is distributed to the supports based on their relative stiffnesses. In cases where the deck must be idealized as a flexible horizontal diaphragm, F_{px} is distributed to the supports based on their respective tributary areas. Decks idealized as rigid diaphragms need only be designed for shear. Decks idealized as flexible diaphragms must be designed for both shear and bending as maximum in-plane deflections of the deck under lateral loads in this case are more than twice the average of the lateral deflections at adjacent support locations. Concrete decks may be designed for shear and bending moments based on the strut-and-tie model (STM), as defined in Article 5.8.2.

In cases where the deck cannot provide horizontal diaphragm action, the Engineer should consider providing lateral bracing to serve as a horizontal diaphragm to transfer the seismic forces.

- W = total weight of the deck, steel girders, and, where applicable, cap beam, plus one-half the column weight within the span under consideration (kip)
- W_{px} = weight of the deck plus one-half of the weight of the steel girders in the span under consideration (kip)

F_{px} in Eq. 6.16.4.2-1 represents the total transverse seismic shear force that the deck is subjected to within a particular span. At skewed supports in structures designed using Strategy Type A, F should be taken as the sum of the absolute values of the components of the transverse and longitudinal base shears parallel to the skew combined, as specified in Article 3.10.8, and as shown in Figure C6.16.4.2-1.

Figure C6.16.4.2-1—Design Deck Shear, F_{px} , at Skewed Supports

Shear keys are typically designed to fuse during the design event earthquake. In lieu of experimental test data, the overstrength ratio for shear key resistance may be obtained from the AASHTO *Guide Specifications for LRFD Seismic Bridge Design*. Thus, where reinforced concrete shear keys are used as a fusing mechanism, the expected lateral resistance of the shear keys, including an overstrength factor, should be taken equal to $1.5V_{ni}$, where V_{ni} is equal to the nominal interface shear resistance determined as specified in Article 5.7.4.

6.16.4.3—Shear Connectors

Stud shear connectors shall be provided along the interface between the deck and the steel girders, or along the interface between the deck and the top of the support cross-frames or diaphragms, or both, as necessary to transfer the seismic forces. If reinforced concrete diaphragms that are connected integrally with the bridge deck are used at support locations, then the shear connectors on the steel girders at those locations need not be designed according to the provisions of this Article.

The shear connectors on the girders assumed effective at the support under consideration shall be taken as those spaced no further than $9t_w$ on each side of the outer projecting element of the bearing stiffeners at that support.

The diameter of the shear connectors within this region shall not be greater than 2.5 times the thickness of the top chord of the cross-frame or the top flange of the diaphragm.

At support locations, shear connectors on the girders or on the support cross-frames or diaphragms, or both, as necessary, shall be designed to resist the combination of shear and axial forces corresponding to the transverse seismic shear force, F_{px} , determined as specified in Article 6.16.4.2.

C6.16.4.3

Stud shear connectors play a significant role in transferring the seismic forces from the deck to the support cross-frames or diaphragms. These seismic forces are transferred to the substructure at support locations. Thus, the shear connectors at support locations are subjected to the largest seismic forces, unless reinforced concrete diaphragms that are connected integrally with the bridge deck are used. Failure of these shear connectors will cause the deck to slip on the top flange of the girder and, thus, alter the seismic load path (Caltrans, 2001) (Carden et al., 2005a) (Bahrami et al., 2010).

The shear center of composite steel-girder superstructures is located above the deck (Zahrai and Bruneau, 1998) (Bahrami et al., 2010). Therefore, during a seismic event, the superstructure will be subjected to torsional moments along the longitudinal axis of the bridge that produce axial forces on the shear connectors in addition to the longitudinal and transverse shears. Lateral deformations during a seismic event produce double curvature in the top chord of the cross-frame, creating axial forces in the shear connectors on that member that must be considered. Experimental and analytical investigations (Carden et al., 2005a and Bahrami et al., 2010) showed that the seismic demand on

The resistance of stud shear connectors subject to combined shear and axial forces shall be evaluated according to the tension–shear interaction equation, given as follows:

$$\left(\frac{N_u}{N_r}\right)^{5/3} + \left(\frac{Q_u}{Q_r}\right)^{5/3} \leq 1.0 \quad (6.16.4.3-1)$$

in which:

$$h_h = h_{eff} - d_h \geq \frac{w_h}{3} \quad (6.16.4.3-2)$$

$$\begin{aligned} N_r &= \text{factored tensile resistance of a single stud shear connector (kip)} \\ &= \phi_{st} N_n \end{aligned} \quad (6.16.4.3-3)$$

$$\begin{aligned} N_n &= \text{nominal tensile resistance of a single stud shear connector (kip)} \\ &= \psi_g \psi_{ed} \frac{A_{nc}}{A_{nco}} N_b \leq A_{sc} F_u \end{aligned} \quad (6.16.4.3-4)$$

ψ_g = group effect modification factor, taken as follows:

- For transverse spacing:

$$\psi_g = 0.95 \text{ for two studs}$$

$$\psi_g = 0.90 \text{ for three studs}$$

- For longitudinal spacing:

$$\psi_g = 0.95 \text{ for spacing} \leq 3h_{eff}$$

$$\psi_g = 1.0 \text{ for spacing} > 3h_{eff}$$

ψ_{ed} = edge modification factor taken as follows:

$$\psi_{ed} = 0.7 + 0.3 \frac{C_a}{1.5h_h} \leq 1.0 \quad (6.16.4.3-5)$$

$$\begin{aligned} A_{nco} &= \text{projected area of concrete failure for a single stud shear connector based on the concrete breakout resistance in tension (in.}^2\text{)} \\ &= 9h_h^2 \end{aligned} \quad (6.16.4.3-6)$$

$$\begin{aligned} N_b &= \text{concrete breakout resistance in tension of a single stud shear connector in cracked concrete (kip)} \\ &= 0.76 \sqrt{f'_c} h_h^{1.5} \end{aligned} \quad (6.16.4.3-7)$$

where:

ϕ_{st} = resistance factor for shear connectors in tension, specified in Article 6.5.4.2

A_{nc} = projected area of concrete for a single stud shear connector or group of connectors approximated from the base of a rectilinear geometric figure

shear connectors that are placed only on the girders at support locations may cause significant damage to the connectors and the deck.

ACI (2014) provides equations for anchorage to concrete of pre- and post-installed anchors subject to shear and axial forces. However, these equations are not used in this Article for the design of shear connectors on slab-on-steel-girder bridges subject to combined shear and axial forces. Mouras et al. (2008) investigated the behavior of shear connectors placed on a steel girder under static and dynamic axial loads. The effects of haunches in reinforced concrete decks, stud length, the number of studs, and the arrangement of the studs in the transverse and longitudinal directions of the bridge were investigated. Based on this investigation, several modifications were recommended to the ACI equations that are reflected in the equations given in this Article. These modifications ensure a ductile response of the shear connectors that is beneficial in seismic applications. The modifications are as follows:

- Provision for adequate embedment of the shear connectors to engage the reinforcement in the deck slab,
- Use of an effective haunch height instead of the effective height given in the ACI equations, and
- Consideration of a group modification factor for longitudinal and transverse spacing. This factor accounts for the overlapping of the cones when studs are closely spaced.

The calculation of the projected area of concrete failure for a single stud shear connector based in the concrete breakout resistance in tension, A_{nco} , is illustrated in Figure C6.16.4.3-1.

$$A_{nco} = (1.5h_h + 1.5h_h)(1.5h_h + 1.5h_h) = 9h_h^2 \quad (C6.16.4.3-1)$$

Figure C6.16.4.3-1—Calculation of A_{nco}

The calculation of A_{nc} for a group of four studs consisting of two rows with two studs per row is illustrated in Figure C6.16.4.3-2.

that results from projecting the failure surface outward $1.5h_h$ from the centerline of the single connector or, in the case of a group of connectors, from a line through a row of adjacent connectors (in.²)

A_{sc} = cross-sectional area of a stud shear connector (in.²)

C_a = smallest distance from center of stud to the edge of the concrete (in.)

d_h = depth of haunch (in.)

F_u = specified minimum tensile strength of a stud shear connector, determined as specified in Article 6.4.4 (ksi)

h_{eff} = effective embedment depth of a stud shear connector (in.)

h_h = effective height of the stud above the top of the haunch to the underside of the head (in.)

N_u = seismic axial force demand per stud at the support cross-frame or diaphragm location under consideration (kip)

Q_u = seismic shear demand per stud at the support cross-frame or diaphragm location under consideration due to the governing orthogonal combination of seismic shears (kip)

Q_r = factored shear resistance of a single stud shear connector, determined as specified in Article 6.10.10.4.1 (kip)

w_h = width of haunch perpendicular to bridge span axis (in.)

$$A_{nc} = (3h_h + x)(3h_h + y) \quad (C6.16.4.3-2)$$

Figure C6.16.4.3-2—Calculation of A_{nc} for a Group of Four Studs (two rows with two studs per row)

Experimental investigation by Bahrami et al. (2010) shows that these equations for the shear and axial resistance and their interaction may be used to satisfactorily determine the resistance of stud shear connectors under the combined loading effects.

For the seismic design of continuous composite spans, shear connectors should be provided throughout the length of the bridge. The requirements of this Article notwithstanding, should shear connectors be omitted in regions of negative flexure, positive attachment of the deck to the support cross-frames or diaphragms located at interior piers must still be provided. Analytical investigation (Carden et al., 2005a) showed that a lack of shear connectors in regions of negative flexure caused the seismic forces to be transferred into the steel girders at points of permanent load contraflexure, causing large weak-axis bending stresses in the girders. In addition, the intermediate cross-frames were subjected to large seismic forces, while the support cross-frames were subjected to smaller forces. This indicated that the seismic load path had been significantly altered.

6.16.4.4—Elastic Superstructures

For an elastic superstructure, support cross-frame members or support diaphragms shall be designed according to the applicable provisions of Articles 6.7, 6.8, or 6.9, or some combination thereof, to remain elastic during a seismic event.

The lateral force, F , for the design of the support cross-frame members or support diaphragms shall be determined as specified in Article 6.16.4.2 for structures designed using Strategy Types A or B, as applicable.

C6.16.4.4

To achieve an elastic superstructure, the various components of the support cross-frames or the support diaphragms, as applicable, must be designed to remain elastic under the forces that are generated during the design earthquake according to the applicable provisions of Articles 6.7, 6.8, or 6.9, or some combination thereof. No other special seismic requirements are specified for these members in this case.

The elastic superstructure can have steel cross-frames of various configurations, steel diaphragms, or reinforced concrete diaphragms. Tennessee DOT has as an alternative used reinforced concrete diaphragms over bent locations. The details of these diaphragms and others are discussed in Bahrami et al. (2010) and Itani and Reno (1995).

APPENDIX A6—FLEXURAL RESISTANCE OF COMPOSITE I-SECTIONS IN NEGATIVE FLEXURE AND NONCOMPOSITE I-SECTIONS WITH COMPACT OR NONCOMPACT WEBS IN STRAIGHT BRIDGES

A6.1—GENERAL

These provisions shall apply only to sections without holes in the tension flange in straight bridges whose supports are normal or skewed not more than 20 degrees from normal, and with intermediate diaphragms or cross-frames placed in contiguous lines parallel to the supports, that satisfy the following requirements:

- the specified minimum yield strengths of the flanges and web do not exceed 70.0 ksi,
- the web satisfies the noncompact slenderness limit:

$$\frac{2 D_c}{t_w} \leq \lambda_{rw} \quad (\text{A6.1-1})$$

and:

- the flanges satisfy the following ratio:

$$\frac{I_{yc}}{I_{yt}} \geq 0.3 \quad (\text{A6.1-2})$$

in which:

λ_{rw} = limiting slenderness ratio for a noncompact web

$$= c_{rw} \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.1-3})$$

c_{rw} = edge-condition coefficient taken as:

$$c_{rw} = \left(3.1 + \frac{5.0}{a_{wc}} \right) \quad (\text{A6.1-4})$$

$$4.6 \leq c_{rw} \leq 5.7$$

a_{wc} = ratio of two times the web area in compression to the area of the compression flange

$$= \frac{2 D_c t_w}{b_{fc} t_{fc}} \quad (\text{A6.1-5})$$

where:

D_c = depth of the web in compression in the elastic range (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.

I_{yc} = moment of inertia of the compression flange of the steel section about the vertical axis in the plane of the web (in.⁴)

CA6.1

The optional provisions of Appendix A6 account for the ability of compact and noncompact web I-sections without holes in the tension flange to develop flexural resistances significantly greater than M_y when the web slenderness, $2D_c/t_w$, is well below the noncompact limit of Eq. A6.1-1, which is a restatement of Eq. 6.10.6.2.3-1, and when sufficient requirements are satisfied with respect to the flange specified minimum yield strengths, the compression flange slenderness, $b_{fc}/2t_{fc}$, and the lateral brace spacing. These provisions also account for the beneficial contribution of the St. Venant torsional constant, J . This may be useful, particularly under construction situations, for sections with compact or noncompact webs having larger unbraced lengths for which additional LTB resistance may be required. Also, for heavy column shapes with $D/b_f < 1.7$, which may be used as beam-columns in steel frames, both the inelastic and elastic buckling resistances are heavily influenced by J .

The potential benefits of the Appendix A6 provisions tend to be small for I-sections with webs that approach the noncompact web slenderness limit of Eq. A6.1-1. For these cases, the simpler and more streamlined provisions of Article 6.10.8 are recommended. The potential gains in economy by using Appendix A6 increase with decreasing web slenderness. The Engineer should give strong consideration to utilizing Appendix A6 for sections in which the web is compact or nearly compact. In particular, the provisions of Appendix A6 are recommended for sections with compact webs, as defined in Article A6.2.1.

The provisions of Appendix A6 are fully consistent with and are a direct extension of the main procedures in Article 6.10.8 in concept and in implementation. The calculation of potential flexural resistances greater than M_y is accomplished through the use of the web plastification parameters, R_{pc} and R_{pt} , of Article A6.2, corresponding to flexural compression and tension, respectively. These parameters are applied much like the web bend-buckling and hybrid girder parameters, R_b and R_h , in the main specification provisions.

I-section members with a specified minimum yield strength of the flanges greater than 70.0 ksi are more likely to be limited by Eq. A6.1-1 and are likely to be controlled by design considerations other than the Strength Load Combinations in ordinary bridge construction. In cases where Eq. A6.1-1 is satisfied with $F_{yc} > 70.0$ ksi, the implications of designing such members in general using a nominal flexural resistance greater than M_y have not been sufficiently studied to merit the use of Appendix A6.

I_{yt} = moment of inertia of the tension flange of the steel section about the vertical axis in the plane of the web (in.⁴)

Otherwise, the section shall be proportioned according to the provisions specified in Article 6.10.8.

Sections designed according to these provisions shall qualify as either compact web sections or noncompact web sections determined as specified in Article A6.2.

A6.1.1—Sections with Discretely Braced Compression Flanges

At the strength limit state, the following requirement shall be satisfied:

$$M_u + \frac{1}{3} f_e S_{xc} \leq \phi_f M_{nc} \quad (\text{A6.1.1-1})$$

where:

- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- f_e = flange lateral bending stress, determined as specified in Article 6.10.1.6 (ksi)
- M_{nc} = nominal flexural resistance based on the compression flange, determined as specified in Article A6.3 (kip-in.)
- M_u = bending moment about the major axis of the cross-section, determined as specified in Article 6.10.1.6 (kip-in.)
- M_{yc} = yield moment with respect to the compression flange, determined as specified in Article D6.2 (kip-in.)
- S_{xc} = elastic section modulus about the major axis of the section to the compression flange, taken as M_{yc}/F_{yc} (in.³)

Eq. A6.1-2 is specified to guard against extremely monosymmetric noncomposite I-sections, in which analytical studies indicate a significant loss in the influence of the St. Venant torsional rigidity, GJ , on the LTB resistance due to cross-section distortion. The influence of web distortion on the LTB resistance is larger for such members. If the flanges are of equal thickness, this limit is equivalent to $b_{fc} \geq 0.67b_{ft}$.

The provisions of Article 6.10.1.8 prevent the nominal flexural resistance of sections with holes in the tension flange from exceeding the moment at first yield as permitted herein.

CA6.1.1

Eq. A6.1.1-1 addresses the effect of combined major-axis bending and compression flange lateral bending using an interaction equation approach. This equation expresses the flexural resistance in terms of the section major-axis bending moment, M_u , and the flange lateral bending stress, f_e , computed from an elastic analysis, applicable within the limits on f_e specified in Article 6.10.1.6 (White and Grubb, 2005).

For adequately braced sections with a compact web and compression flange, Eqs. A6.1.1-1 and A6.1.2-1 are generally a conservative representation of the resistance obtained by procedures that address the effect of flange wind moments given in Article 6.10.3.5.1 of AASHTO (1998). In the theoretical limit that the web area becomes negligible relative to the flange area, these equations closely approximate the results of an elastic-plastic section analysis in which a fraction of the width from the tips of the flanges is deducted to accommodate the flange lateral bending. The conservatism of these equations relative to the theoretical solution increases with increasing $D_{cp}t_w/b_{fc}t_{fc}$, f_e , and/or $|D_{cp} - D_c|$. The conservatism at the limit on f_e specified by Eq. 6.10.1.6-1 ranges from about three to ten percent for practical flexural I-sections.

The multiplication of f_e by S_{xc} in Eq. A6.1.1-1 and by S_{xt} in Eq. A6.1.2-1 stems from the derivation of these equations, and is explained further in White and Grubb (2005). These equations may be expressed in a stress format by dividing both sides by the corresponding elastic section modulus, in which case, Eq. A6.1.1-1 reduces effectively to Eqs. 6.10.3.2.1-2 and 6.10.8.1.1-1 in the limit that the web approaches its noncompact slenderness limit. Correspondingly, Eq. A6.1.2-1 reduces effectively to Eqs. 6.10.7.2.1-2 and 6.10.8.1.2-1 in this limit.

The elastic section moduli, S_{xc} in this Article and S_{xt} in Article A6.1.2, are defined as M_{yc}/F_{yc} and M_{yt}/F_{yt} , respectively, where M_{yc} and M_{yt} are calculated as specified in Article D6.2. This definition is necessary so that for a composite section with a web proportioned precisely at the noncompact limit given by Eq. A6.1-1, the flexural resistance predicted by Appendix A6 is approximately the same as that predicted by Article 6.10.8. Differences between these predictions are

due to the simplifying assumptions of $J = 0$ versus $J \neq 0$ in determining the elastic LTB resistance and the limiting unbraced length L_r , the use of $k_c = 0.35$ versus the use of k_c from Eq. A6.3.2-6 in determining the limiting slenderness for a noncompact flange, and the use of a slightly different definition for F_{yf} . The maximum potential flexural resistance, shown as F_{max} in Figure C6.10.8.2.1-1, is defined in terms of the flange stresses as $R_h F_{yf}$ for a section with a web proportioned precisely at the noncompact web limit and designed according to the provisions of Article 6.10.8, where R_h is the hybrid factor defined in Article 6.10.1.10.1. As discussed in Article 6.10.1.1.1a, for composite sections, the elastically computed flange stress to be compared to this limit is to be taken as the sum of the stresses caused by the loads applied separately to the steel, short-term composite and long-term composite sections. The resulting provisions of Article 6.10.8 are a reasonable strength prediction for slender-web sections in which the web is proportioned precisely at the noncompact limit. By calculating S_{xc} and S_{xt} in the stated manner, elastic section moduli are obtained that, when multiplied by the corresponding flexural resistances predicted from Article 6.10.8 for the case of a composite slender-web section proportioned precisely at the noncompact web limit, produce approximately the same flexural resistances as predicted in Appendix A6.

For composite sections with web slenderness values that approach the compact web limit of Eq. A6.2.1-2, the effects of the loadings being applied to the different steel, short-term and long-term sections are nullified by the yielding within the section associated with the development of the stated flexural resistance. Therefore, for compact web sections, these Specifications define the maximum potential flexural resistance, shown as M_{max} in Figure C6.10.8.2.1-1, as the plastic moment M_p , which is independent of the effects of the different loadings.

A6.1.2—Sections with Discretely Braced Tension Flanges

At the strength limit state, the following requirement shall be satisfied:

$$M_u + \frac{1}{3} f_t S_{xt} \leq \phi_f M_{nt} \quad (\text{A6.1.2-1})$$

where:

- M_{nt} = nominal flexural resistance based on tension yielding, determined as specified in Article A6.4 (kip-in.)
- M_{yt} = yield moment with respect to the tension flange, determined as specified in Article D6.2 (kip-in.)

CA6.1.2

Eq. A6.1.2-1 parallels Eq. A6.1.1-1 for discretely braced compression flanges, but applies to the case of discretely braced flanges in flexural tension due to the major-axis bending moment.

When f_t is equal to zero and M_{yc} is less than or equal to M_{yt} , the flexural resistance based on the tension flange does not control and Eq. A6.1.2-1 need not be checked. The web plastification factor for tension-flange yielding, R_{pt} , from Article A6.2 also need not be computed for this case.

S_{xt} = elastic section modulus about the major axis of the section to the tension flange taken as M_{yt}/F_{yt} (in.³)

A6.1.3—Sections with Continuously Braced Compression Flanges

At the strength limit state, the following requirement shall be satisfied:

$$M_u \leq \phi_f R_{pc} M_{yc} \quad (\text{A6.1.3-1})$$

where:

M_{yc} = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.)

R_{pc} = web plastification factor for the compression flange determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

A6.1.4—Sections with Continuously Braced Tension Flanges

At the strength limit state, the following requirement shall be satisfied:

$$M_u \leq \phi_f R_{pt} M_{yt} \quad (\text{A6.1.4-1})$$

where:

M_{yt} = yield moment with respect to the tension flange, determined as specified in Article D6.2 (kip-in.)

R_{pt} = web plastification factor for the tension flange, determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

A6.2—WEB PLASTIFICATION FACTORS

A6.2.1—Compact Web Sections

Sections that satisfy the following requirement shall qualify as compact web sections:

$$\frac{2D_{cp}}{t_w} \leq \lambda_{pw(D_{cp})} \quad (\text{A6.2.1-1})$$

in which:

$\lambda_{pw(D_{cp})}$ = limiting slenderness ratio for a compact web corresponding to $2D_{cp}/t_w$

CA6.1.3

Flange lateral bending need not be considered in continuously braced flanges, as discussed further in Article C6.10.1.6.

CA6.2.1

Eq. A6.2.1-1 ensures that the section is able to develop the full plastic moment capacity M_p provided that other flange slenderness and lateral-torsional bracing requirements are satisfied. This limit is significantly less than the noncompact web limit shown in Table C6.10.1.10.2-2. It is generally satisfied by rolled I-shapes, but typically not by the most efficient built-up sections.

Eq. A6.2.1-2 is a web compactness limit that accounts for the higher demands on the web in noncomposite monosymmetric I-sections and in composite I-sections in negative bending with larger shape factors, M_p/M_y (White and Barth, 1998) (Barth et al., 2005). This updated web compactness limit eliminates the need for providing an interaction equation between the web and flange compactness requirements (AASHTO, 1998; 2002). Eq. A6.2.1-2

$$= \frac{\sqrt{\frac{E}{F_{yc}}}}{\left(0.54 \frac{M_p}{R_h M_y} - 0.09\right)^2} \leq \lambda_{rw} \left(\frac{D_{cp}}{D_c}\right) \quad (\text{A6.2.1-2})$$

λ_{rw} = limiting slenderness ratio for a noncompact web

$$= c_{rw} \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.2.1-3})$$

c_{rw} = edge-condition coefficient, taken as:

$$c_{rw} = \left(3.1 + \frac{5.0}{a_{wc}}\right) \quad (\text{A6.2.1-4})$$

$$4.6 \leq c_{rw} \leq 5.7$$

a_{wc} = ratio of two times the web area in compression to the area of the compression flange

$$= \frac{2 D_c t_w}{b_f t_{fc}} \quad (\text{A6.2.1-5})$$

where:

D_c = depth of the web in compression in the elastic range (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.

D_{cp} = depth of the web in compression at the plastic moment determined as specified in Article D6.3.2 (in.)

M_y = yield moment, taken as the smaller of M_{yc} and M_{yt} determined as specified in Article D6.2 (kip-in.)

R_h = hybrid factor, determined as specified in Article 6.10.1.10.1

The web plastification factors shall be taken as:

$$R_{pc} = \frac{M_p}{M_{yc}} \quad (\text{A6.2.1-6})$$

$$R_{pt} = \frac{M_p}{M_{yt}} \quad (\text{A6.2.1-7})$$

where:

M_p = plastic moment, determined as specified in Article D6.1 (kip-in.)

M_{yc} = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.)

M_{yt} = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

reduces to the previous web compactness limit given by Equation 6.10.4.1.2-1 in AASHTO (1998) when $M_p/M_y = 1.12$, which is representative of the shape factor for doubly symmetric noncomposite I-sections. The previous web compactness limit is retained in Eq. 6.10.6.2.2-1 for composite sections in positive flexure since research does not exist to quantify the web compactness requirements for these types of sections with any greater precision, and also since most composite sections in positive flexure easily satisfy this requirement.

The compactness restrictions on the web imposed by Eq. A6.2.1-2 are approximately the same as the requirements implicitly required for development of the plastic moment resistance, M_p , by the Q formula in AASHTO (1998) and White et al. (2006). Both of these requirements are plotted as a function of M_p/M_y for $F_{yc} = 50.0$ ksi in Figure CA6.2.1-1.

Figure CA6.2.1-1—Web Compactness Limits as a Function of M_p/M_y from the AASHTO (1998) Q formula and from Eq. A6.2.1-2 for $F_{yc} = 50.0$ ksi

For a compact web section, the maximum potential moment resistance, represented by M_{max} in Figure C6.10.8.2.1-1, is simply equal to M_p . Eqs. A6.2.1-6 and A6.2.1-7 capture this attribute and eliminate the need to repeat the subsequent flexural resistance equations in a nearly identical fashion for compact and noncompact web sections. For a compact web section, the web plastification factors are equivalent to the cross-section shape factors.

R_{pc} = web plastification factor for the compression flange

R_{pt} = web plastification factor for tension flange yielding

A6.2.2—Noncompact Web Sections

CA6.2.2

Sections that do not satisfy the requirement of Eq. A6.2.1-1, but for which the web slenderness satisfies the following requirement:

$$\lambda_w \leq \lambda_{rw} \quad (\text{A6.2.2-1})$$

shall qualify as noncompact web sections, in which:

λ_w = slenderness ratio for the web, based on the elastic moment

$$= \frac{2 D_c}{t_w} \quad (\text{A6.2.2-2})$$

λ_{rw} = limiting slenderness ratio for a noncompact web

$$= c_{rw} \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.2.2-3})$$

c_{rw} = edge-condition coefficient, taken as:

$$c_{rw} = \left(3.1 + \frac{5.0}{a_{wc}} \right) \quad (\text{A6.2.2-4})$$

$$4.6 \leq c_{rw} \leq 5.7$$

a_{wc} = ratio of two times the web area in compression to the area of the compression flange

$$= \frac{2 D_c t_w}{b_{fc} t_{fc}} \quad (\text{A6.2.2-5})$$

D_c = depth of the web in compression in the elastic range (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.

The web plastification factors shall be taken as:

$$R_{pc} = \left[1 - \left(1 - \frac{R_h M_{yc}}{M_p} \right) \left(\frac{\lambda_w - \lambda_{pw}(D_c)}{\lambda_{rw} - \lambda_{pw}(D_c)} \right) \right] \frac{M_p}{M_{yc}} \leq \frac{M_p}{M_{yc}} \quad (\text{A6.2.2-6})$$

$$R_{pt} = \left[1 - \left(1 - \frac{R_h M_{yt}}{M_p} \right) \left(\frac{\lambda_w - \lambda_{pw}(D_c)}{\lambda_{rw} - \lambda_{pw}(D_c)} \right) \right] \frac{M_p}{M_{yt}} \leq \frac{M_p}{M_{yt}} \quad (\text{A6.2.2-7})$$

Eqs. A6.2.2-6 and A6.2.2-7 account for the influence of the web slenderness on the maximum potential flexural resistance, M_{max} in Figure C6.10.8.2.1-1, for noncompact web sections. As $2D_c/t_w$ approaches the noncompact web limit λ_{rw} , R_{pc} and R_{pt} approach values equal to R_h and the maximum potential flexural resistance expressed within the subsequent limit state equations approaches a limiting value of $R_h M_y$. As $2D_c/t_w$ approaches the compact web limit $\lambda_{pw}(D_c)$, Eqs. A6.2.2-6 and A6.2.2-7 define a smooth

where:

$$\begin{aligned}\lambda_{pw(D_c)} &= \text{limiting slenderness ratio for a compact web} \\ &\quad \text{corresponding to } 2D_c/t_w \\ &= \lambda_{pw(D_{cp})} \left(\frac{D_c}{D_{cp}} \right) \leq \lambda_{rw} \quad (\text{A6.2.2-8})\end{aligned}$$

transition in the maximum potential flexural resistance, expressed by the subsequent limit state equations, from M_y to the plastic moment resistance M_p . For a compact web section, the web plastification factors R_{pc} and R_{pt} are simply the section shape factors corresponding to the compression and tension flanges, M_p/M_{yc} and M_p/M_{yt} . The subsequent flexural resistance equations are written using R_{pc} and R_{pt} for these types of sections, rather than expressing the maximum resistance simply as M_p , to avoid repetition of strength equations that are otherwise identical.

In Eqs. A6.2.2-6 and A6.2.2-7, explicit maximum limits of M_p/M_{yc} and M_p/M_{yt} are placed on R_{pc} and R_{pt} , respectively. As a result, the larger of the base resistances, $R_{pc}M_{yc}$ or $R_{pt}M_{yt}$, is limited to M_p for a highly monosymmetric section in which M_{yc} or M_{yt} can be greater than M_p . The limits on I_{yc}/I_{yt} given in Article 6.10.2.2 will tend to prevent the use of extremely monosymmetric sections that have M_{yc} or M_{yt} values greater than M_p . The upper limits on R_{pc} and R_{pt} have been provided to make Eqs. A6.2.2-6 and A6.2.2-7 theoretically correct in these extreme cases, even though the types of monosymmetric sections where these limits control will not likely occur.

Eq. A6.2.2-8 converts the web compactness limit given by Eq. A6.2.1-2, which is defined in terms of D_{cp} , to a value that can be used consistently in terms of D_c in Eqs. A6.2.2-6 and A6.2.2-7. In cases where $D_c/D > 0.5$, D_{cp}/D is typically larger than D_c/D ; therefore, $\lambda_{pw(D_c)}$ is smaller than $\lambda_{pw(D_{cp})}$. However, when $D_c/D < 0.5$, D_{cp}/D is typically smaller than D_c/D and $\lambda_{pw(D_c)}$ is larger than $\lambda_{pw(D_{cp})}$. In extreme cases where D_c/D is significantly less than 0.5, the web slenderness associated with the elastic cross-section, $2D_c/t_w$, can be larger than λ_{rw} while that associated with the plastic cross-section, $2D_{cp}/t_w$, can be smaller than $\lambda_{pw(D_{cp})}$ without the upper limit of $\lambda_{rw}(D_{cp}/D_c)$

that is placed on this value. That is, the elastic web is classified as slender while the plastic web is classified as compact. In these cases, the compact web limit is defined as $\lambda_{pw(D_c)} = \lambda_{rw}(D_{cp}/D_c)$. This is a

conservative approximation aimed at protecting against the occurrence of bend-buckling in the web prior to reaching the section plastic resistance.

The ratio D_c/D is generally greater than 0.5 for noncomposite sections with a smaller flange in compression, such as typical composite I-girders in positive bending before they are made composite.

A6.3—FLEXURAL RESISTANCE BASED ON THE COMPRESSION FLANGE

A6.3.1—General

Eq. A6.1.1-1 shall be satisfied for both local buckling and LTB using the appropriate value of M_{nc} determined for each case as specified in Articles A6.3.2 and A6.3.3, respectively.

CA6.3.1

All of the I-section compression flange flexural resistance equations of these Specifications are based consistently on the logic of identifying the two anchor points shown in Figure C6.10.8.2.1-1 for the case of uniform major-axis bending. Anchor point 1 is located at the length $L_b = L_p$ for LTB or the flange slenderness $b_{fc}/2t_{fc} = \lambda_{pf}$ for flange local buckling (FLB) corresponding to development of the maximum potential flexural resistance, labeled as F_{max} or M_{max} in the figure, as applicable. Anchor point 2 is located at the length L_r or flange slenderness λ_{rf} for which the inelastic and elastic LTB or flange-flange local buckling resistances are the same.

In Article A6.3.2, this resistance is taken as $R_b F_{yr} S_{xc}$, where F_{yr} is taken as the smaller of $0.7F_{yc}$, F_{yw} , or $R_b F_{yt} S_{xt}/S_{xc}$, but not smaller than $0.5F_{yc}$. The first two of these resistances are the same as in Article 6.10.8.2.2. The third resistance expression, $R_b F_{yt} S_{xt}/S_{xc}$, which is simply the elastic compression-flange stress at the cross-section moment $R_b F_{yt} S_{xt} = R_b M_{yt}$, captures the effects of significant early tension-flange yielding in sections with a small depth of web in compression. In sections that have this characteristic, the early tension-flange yielding invalidates the elastic LTB equation on which the noncompact bracing limit L_r is based, and also makes the corresponding elastic FLB equation less accurate due to potential significant inelastic redistribution of stresses to the compression flange. The limit $R_b F_{yt} S_{xt}/S_{xc}$ rarely controls for bridge I-girders, but it may control in some instances of pier negative moment sections in composite continuous spans, prior to the section becoming composite, in which the top flange is significantly smaller than the bottom flange. For welded sections in Article A6.3.3.1, this resistance is taken as $R_b F_{yr} S_{xc}$, where F_{yr} is taken as $0.5F_{yc}$ to account for the combined effects of residual stresses and geometric imperfections on the LTB resistance; for rolled sections, F_{yr} is taken as $0.7F_{yc}$. For $L_b > L_r$ or $b_{fc}/2t_{fc} > \lambda_{rf}$, the LTB and FLB resistances are governed by elastic buckling. However, the elastic FLB resistance equations are not specified explicitly in these provisions since the limits of Article 6.10.2.2 preclude elastic FLB for specified minimum yield strengths up to and including $F_{yc} = 70.0$ ksi, which is the limiting yield strength for the application of the provisions of Appendix A6.

For unbraced lengths subjected to moment gradient, the LTB resistances for the case of uniform major-axis bending are simply scaled by the moment-gradient modifier C_b , with the exception that the LTB resistance is capped at F_{max} or M_{max} , as illustrated by the dashed line in Figure C6.10.8.2.1-1. The maximum unbraced length at which the LTB resistance is equal to F_{max} or M_{max} under a moment gradient may be determined from

A6.3.2—Local Buckling Resistance

The flexural resistance based on compression FLB shall be taken as:

- If $\lambda_f \leq \lambda_{pf}$, then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{A6.3.2-1})$$

- Otherwise:

$$M_{nc} = \left[1 - \left(1 - \frac{F_{yr} S_{xc}}{R_{pc} M_{yc}} \right) \left(\frac{\lambda_f - \lambda_{pf}}{\lambda_{pf} - \lambda_{pf}} \right) \right] R_{pc} M_{yc} \quad (\text{A6.3.2-2})$$

in which:

λ_f = slenderness ratio for the compression flange

$$= \frac{b_{fc}}{2t_{fc}} \quad (\text{A6.3.2-3})$$

λ_{pf} = limiting slenderness ratio for a compact flange

$$= 0.38 \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.3.2-4})$$

λ_{nf} = limiting slenderness ratio for a noncompact flange

$$= 0.95 \sqrt{\frac{Ek_c}{F_{yr}}} \quad (\text{A6.3.2-5})$$

k_c = FLB coefficient

- For built-up sections:

$$= \frac{4}{\sqrt{\frac{D}{t_w}}} \quad (\text{A6.3.2-6})$$

$$0.35 \leq k_c \leq 0.76$$

- For rolled shapes:

$$= 0.76$$

where:

F_{yr} = compression-flange stress at the onset of nominal yielding within the cross-section,

Article D6.4.1 or D6.4.2, as applicable. The FLB resistance for moment gradient cases is the same as that for the case of uniform major-axis bending, neglecting the relatively minor influence of moment gradient effects.

CA6.3.2

Eq. A6.3.2-4 defines the slenderness limit for a compact flange, whereas Eq. A6.3.2-5 gives the slenderness limit for a noncompact flange. The nominal flexural resistance of a section with a compact flange is independent of the flange slenderness, whereas the flexural resistance of a section with a noncompact flange is expressed as a linear function of the flange slenderness as illustrated in Figure C6.10.8.2.1-1. The compact flange slenderness limit is the same as specified in AISC (2022b), AASHTO (1998), and Article 6.10.8.2.2. For different grades of steel, this slenderness limit is specified in Table C6.10.8.2.2-1. All current ASTM W shapes except W21×48, W14×99, W14×90, W12×65, W10×12, W8×31, W8×10, W6×15, W6×9 and W6×8.5 have compact flanges at $F_y \leq 50.0$ ksi.

Eq. A6.3.2-6 for the FLB coefficient comes from the implementation of Johnson's (1985) research in AISC (2022b). The value $k_c = 0.35$ is a lower bound to values back-calculated by equating the resistances from these provisions, or those of Article 6.10.8.2.2 where this Article is not applicable, to the measured resistances from Johnson's and other tests such as those conducted by Basler et al. (1960). Tests ranging from $D/t_w = 72$ to 245 were considered. One of the tests from Basler et al. (1960) with $D/t_w = 185$, in which the compression flange was damaged in a previous test and then subsequently straightened and cut-back to a narrower width prior to retesting, exhibited a back-calculated k_c of 0.28. This test was not considered in selecting the lower bound. Other tests by Johnson (1985) that had higher D/t_w values exhibited back-calculated k_c values greater than 0.4. A value of $k_c = 0.43$ is obtained for ideally simply supported boundary conditions at the web-flange juncture (Timoshenko and Gere, 1961). Smaller values of k_c correspond to the fact that web local buckling in more slender webs tends to destabilize the compression flange. The value of $k_c = 0.76$ for rolled shapes is taken from AISC (2022b).

including residual stress effects, but not including compression flange lateral bending, taken as the smaller of $0.7F_{yc}$, $R_h F_{yt} S_{xt}/S_{xc}$ and F_{yw} , but not less than $0.5F_{yc}$

M_{yc} = yield moment with respect to the compression flange, determined as specified in Article D6.2 (kip-in.)

M_{yt} = yield moment with respect to the tension flange, determined as specified in Article D6.2 (kip-in.)

R_h = hybrid factor, determined as specified in Article 6.10.1.10.1

R_{pc} = web plastification factor for the compression flange, determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

S_{xc} = elastic section modulus about the major axis of the section to the compression flange, taken as M_{yc}/F_{yc} (in.³)

S_{xt} = elastic section modulus about the major axis of the section to the tension flange, taken as M_{yt}/F_{yt} (in.³)

A6.3.3—LTB Resistance

A6.3.3.1—General

These provisions shall apply to general noncomposite unbraced lengths of I-section members as well as composite unbraced lengths of I-section members.

These provisions are not applicable for I-section members subjected to single-curvature bending in which the flange in flexural compression is continuously braced within the entire unbraced length under consideration. For these types of unbraced lengths, the continuously braced flange shall be checked by the provisions of Article 6.10.7.1, 6.10.7.2, or A6.1.4, as applicable.

If a member has a slender web at any location along the unbraced length under consideration, it shall be considered as a slender-web member along the entire unbraced length and Article 6.10.8.2.3 shall apply. Otherwise, in lieu of a more refined analysis, the nominal flexural resistance based on LTB shall be calculated at the cross-section where $M_u/R_{pc}M_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections, and shall be taken as:

- If $L_b \leq L_p$, then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{A6.3.3.1-1})$$

- If $L_p < L_b \leq L_r$, then:

$$M_{nc} = C_b \left[1 - \left(1 - \frac{F_{yt} S_{xc}}{R_{pc} M_{yc}} \right) \left(\frac{L_b - L_p}{L_r - L_p} \right) \right] R_{pc} M_{yc} \leq R_{pc} M_{yc} \quad (\text{A6.3.3.1-2})$$

- If $L_b > L_r$, then:

CA6.3.3.1

The handling of general single- or reverse curvature bending on nonprismatic unbraced lengths in these provisions, including steps in F_{yc} along the length, is based in general on the procedures in AISC Design Guide 25 (White et al., 2021a).

For compact- and noncompact-web section members, all the cross-sections of the unbraced length are equally critical when Eq. A6.3.3.1-3 governs and $M_{nc} < R_{pc}M_{yc}$ because, for elastic LTB, there is only one γ_e . This γ_e is the multiplier by which the calculated design moments would need to be scaled to reach the theoretical elastic LTB load level as described further in Article CA6.3.3.3. For cases where the elastic LTB resistance is calculated directly from an elastic eigenvalue buckling analysis, γ_e is the smallest, or controlling, eigenvalue obtained from the buckling solution.

For unbraced lengths ranging from the simplest case of homogeneous prismatic members with noncompact or compact webs, where R_{pc} is a constant equal to the effective shape factor of the cross-section and equal to M_p/M_{yc} for a section with a compact web, and with constant $R_{pc}M_{yc}$ throughout the unbraced length under consideration, through the most complex cases involving variable web depth members with steps in the cross-section along the length, including steps in the yield strength of the component plates, where R_{pc} generally varies along the unbraced length:

- The largest M_u/M_{nc} for LTB occurs at the cross-section having the largest $M_u/R_{pc}M_{yc}$ when Eq. A6.3.3.1-1 governs.
- All the cross-sections of the unbraced length are equally critical when Eq. A6.3.3.1-3 governs, unless

$$M_{nc} = F_e S_{xc} \leq R_{pc} M_{yc} \quad (\text{A6.3.3.1-3})$$

in which:

L_p = limiting unbraced length to achieve the nominal flexural resistance $R_{pc} M_{yc}$ under uniform bending (in.)

$$= 1.1 r_t \sqrt{\frac{E}{F_{yc}}} \quad (\text{A6.3.3.1-4})$$

L_r = limiting unbraced length corresponding to the nominal onset of yielding effects under uniform bending with consideration of compression-flange residual stresses and geometric imperfections (in.)

$$= 1.95 r_t \frac{E}{F_{yr}} \sqrt{\frac{J}{S_{xc} h} + \sqrt{\left(\frac{J}{S_{xc} h}\right)^2 + 6.76 \left(\frac{F_{yr}}{E}\right)^2}} \quad (\text{A6.3.3.1-5})$$

J = St. Venant torsional constant (in.⁴)

$$= \frac{Dt_w^3}{3} + \frac{b_{fc} t_{fc}^3}{3} \left(1 - 0.63 \frac{t_{fc}}{b_{fc}}\right) + \frac{b_{ft} t_{ft}^3}{3} \left(1 - 0.63 \frac{t_{ft}}{b_{ft}}\right) \quad (\text{A6.3.3.1-6})$$

where:

b_{fc} = width of the compression flange (in.)
 b_{ft} = width of the tension flange (in.)
 h = depth between the centerline of the flanges (in.)
 r_t = radius of gyration for LTB, calculated as specified in Article A6.3.3.2 or A6.3.3.3, as applicable (in.)
 t_{fc} = thickness of the compression flange (in.)
 t_{ft} = thickness of the tension flange (in.)
 t_w = web thickness (in.)
 C_b = moment-gradient modifier, calculated as specified in Article A6.3.3.2 or A6.3.3.3, as applicable
 D = web depth (in.)
 F_e = elastic LTB stress, calculated as specified in Article A6.3.3.2 or A6.3.3.3, as applicable (ksi)
 F_{yc} = specified minimum yield strength of the compression flange (ksi)
 F_{yr} = compression-flange stress at the onset of nominal yielding, including residual stress and geometric imperfection effects, but not including compression-flange lateral bending, taken as $0.5F_{yc}$ for welded sections, and as $0.7F_{yc}$ for rolled sections (ksi)

the moment at elastic LTB becomes greater than the plateau strength, $R_{pc} M_{yc}$, in which case the largest M_u/M_{nc} for LTB occurs at the cross-section having the largest $M_u/R_{pc} M_{yc}$.

Eq. A6.3.3.1-4 defines the compact unbraced length limit for a member subjected to uniform major-axis bending, whereas Eq. A6.3.3.1-5 gives the corresponding noncompact unbraced length limit. The flexural resistance of a member braced at or below the compact limit is independent of the unbraced length, whereas it is expressed as a linear function of the unbraced length for lengths between the compact and noncompact limits as illustrated in Figure C6.10.8.2.1-1. The compact bracing limit of Eq. A6.3.3.1-4 is the same as the corresponding limit in Eq. 6.10.8.2.3a-4 and is discussed in Article C6.10.8.2.3a. This limit is consistent with the value employed for general I-section members in AISC (2022b) and is slightly larger than the limit employed in prior editions of the AASHTO *LRFD Bridge Design Specifications*. For welded sections, the definition of F_{yr} in Eqs. A6.3.3.1-2 and A6.3.3.1-5 is changed to $0.5F_{yc}$ from a variable value, often equal to $0.7F_{yc}$ in previous Specifications, to provide a more uniform level of reliability consistent with the target levels herein and in AISC (2022b) (Subramanian et al., 2018) (Slein et al., 2021). The value $0.7F_{yc}$ is retained for rolled sections.

Where a more refined estimate of the LTB resistance accounting for end restraint from adjacent unbraced lengths and/or connection details is desired, the effective unbraced length, $K\ell_b$, may be substituted for the length, L_b , in the LTB equations of this article. Alternatively, the LTB resistance may be based on a direct buckling analysis. Article CD6.6.4 provides guidance pertaining to this type of analysis. Ziemian (2010) and Nethercot and Trahair (1976) present a simple hand method for calculation of elastic LTB effective length factors. The use of half-round I-girder bearing stiffeners at supports can provide increased torsional warping restraint at one or more ends of an unbraced length containing such stiffeners resulting in an increased elastic lateral-torsional buckling resistance, which may be particularly beneficial when investigating stability during construction, and also a smaller effective unbraced length for computing the nominal lateral-torsional buckling resistance, M_{nc} . The increased elastic lateral-torsional buckling resistance can also result in smaller amplification of first-order flange lateral bending stresses in the compression flange within the unbraced length under consideration according to the provisions of Article 6.10.1.6. When such stiffeners are utilized, a lower-bound effective length factor of 0.8 may be assumed when half-round bearing stiffeners are present at both ends of the unbraced length under consideration, or 0.9 when half-round bearing stiffeners are present at only one end of the unbraced length. Quadrato et al. (2014) present an approach to calculate more refined and less conservative values of the effective length factor for such cases.

Note that the most economical solution is not necessarily achieved by limiting the unbraced length to L_p .

- L_b = unbraced length (in.)
 M_u = factored major-axis bending moment at the cross-section under consideration (kip-in.)
 M_{yc} = yield moment with respect to the compression flange, determined as specified in Article D6.2 (kip-in.)
 R_{pc} = web plastification factor for the compression flange at the cross-section under consideration, determined as specified in Article A6.2.1 or Article A6.2.2, as applicable
 S_{xc} = for Eq. A6.3.3.1-5, elastic section modulus about the major axis of the section to the compression flange. Otherwise, taken as M_{yc}/F_{yc} (in.³)

Article A6.3.3.2 shall apply for determining the LTB parameters C_b , F_e , and r_t for prismatic unbraced lengths. Article A6.3.3.3 shall apply for determining these parameters for nonprismatic unbraced lengths.

For noncomposite unbraced lengths of members subjected to reverse curvature bending, the maximum $M_u/R_{pc}M_{yc}$ shall be determined considering both flanges. For unbraced lengths subjected to reverse curvature bending and in which one of the flanges is continuously braced, the maximum $M_u/R_{pc}M_{yc}$ shall be determined considering only the flange that is not continuously braced. In this case, the continuously braced flange shall be checked by the provisions of Article 6.10.7.1, 6.10.7.2, or A6.1.4, as applicable.

A6.3.3.2—LTB Parameters for Prismatic Unbraced Lengths

The moment-gradient modifier, C_b , may be calculated as specified in Article 6.10.8.2.3b.

The elastic LTB stress, F_e , at the governing cross-section shall be taken as:

$$F_e = \frac{C_b \pi^2 E}{(L_b/r_t)^2} \sqrt{1 + 0.078 \frac{J}{S_{xc} h}} \left(L_b/r_t \right)^2 \quad (\text{A6.3.3.2-1})$$

where:

- S_{xc} = elastic section modulus about the major axis of the section to the compression flange (in.³)

The radius of gyration for LTB, r_t , at the governing cross-section may be taken as specified in Eq. 6.10.8.2.3b-3.

Where C_b is greater than 1.0, the LTB resistance alternatively may be calculated by the equivalent procedures specified in Article D6.4.2, using the parameters calculated as specified herein.

Setting $L_b < L_p$ ensures that the member can achieve the plateau strength, $R_{pc}M_{yc}$, when $C_b = 1.0$. Less restrictive unbraced lengths achieve the plateau strength when C_b is greater than 1.0. Furthermore, the most economical design may be one in which the plateau strength is not achieved, particularly when the moment-gradient modifier, C_b , is close to 1.0.

Eq. A6.3.3.1-6 is taken from El Darwish and Johnston (1965) and provides an accurate approximation of the St. Venant torsional constant, J , neglecting the effect of the web-to-flange fillets. For a compression or tension flange with a ratio, b_f/t_f , greater than 15, the term in parentheses given in Eq. A6.3.3.1-6 for that flange may be taken equal to one. Equations from El Darwish and Johnston (1965) employed in the calculation of AISC (2023) manual values for J and including the effect of the web-to-flange fillets are provided in Seaburg and Carter (1997).

For cases in single-curvature bending where continuous bracing of a flange subjected to compression ends, the unbraced length is to be taken as the distance from the end of the continuous bracing to the adjacent location of a discrete brace; otherwise, the unbraced length is to be taken as the full unbraced length between the discrete brace locations.

CA6.3.3.2

Eq. A6.3.3.2-1 gives effectively the exact beam-theory based solution for the elastic torsional buckling of a doubly symmetric I-section (Timoshenko and Gere, 1961) for the case of uniform major-axis bending when C_b is equal to 1.0 and when r_t is defined as specified by Eq. C6.10.8.2.3b-4. Eq. 6.10.8.2.3b-3 is a simplification of this r_t equation obtained by assuming $D = h = d$. For sections with thick flanges, Eq. 6.10.8.2.3b-3 gives a r_t value that can be as much as three to four percent conservative relative to the exact equation. Use of Eq. C6.10.8.2.3b-4 is permitted for software calculations or if the Engineer requires a more precise calculation of the elastic LTB resistance. The format of Eq. A6.3.3.2-1 and the corresponding L_r limit of Eq. A6.3.3.1-5 are particularly convenient for design since the terms L_b , r_t , J , S_{xc} and h are familiar and are easily calculated or can be readily obtained from design tables. Also, by simply setting J to zero, Eq. A6.3.3.2-1 reduces to Eq. 6.10.8.2.3b-2 and Eq. A6.3.3.1-5 reduces to Eq. 6.10.8.2.3a-5.

Eq. A6.3.3.2-1 also gives an accurate approximation of the exact beam-theory based solution for elastic LTB of singly symmetric I-section members. For the case of $J > 0$ and uniform bending, and considering I-sections with $D/b_f > 2$, $b_{fc}/2t_{fc} > 5$ and $L_b = L_r$, the error in Eq. A6.3.3.2-1 relative to the exact beam-theory solution ranges from 12 percent conservative to two percent unconservative (White and Jung, 2003). A comparable I_{yc} -based equation in

AASHTO (1998) gives maximum unconservative errors of approximately 14 percent for the same set of parameters studied. For the unusual case of a noncomposite compact or noncompact web section with $I_{yc}/I_{yt} > 1.5$ and $D/b_{fc} < 2$, $D/b_{ft} < 2$ or $b_{ft}/t_{ft} < 10$, consideration should be given to using the exact beam-theory equations (White and Jung, 2003) to obtain a more accurate solution. Otherwise, J from Eq. A6.3.3.1-6 may be factored by 0.8 to account for the tendency of Eq. A6.3.3.2-1 to overestimate the LTB resistance in such cases. For highly singly symmetric I-sections with a smaller compression flange or for composite I-sections in negative flexure, both Eq. A6.3.3.2-1 and the prior I_{yc} -based equation in AASHTO (1998) are somewhat conservative compared to rigorous beam-theory based solutions. This is due to the fact that these equations do not account for the restraint against lateral buckling of the compression flange provided by the larger tension flange, or the deck at the level of the top flange in a composite I-girder.

The effect of a variation in the moment along the length between brace points is accounted for by using the moment-gradient modifier, C_b . Article C6.10.8.2.3b discusses C_b in detail. Where C_b is greater than 1.0, indicating the presence of a moment gradient, the LTB resistances may alternatively be calculated by the equivalent procedures specified in Article D6.4.2. Both the equations in this Article and in Article D6.4.2 permit the plateau strength, M_{max} , in Figure C6.10.8.2.1-1 to be reached at larger unbraced lengths when C_b is greater than 1.0. The procedures in Article D6.4.2 allow the Engineer to focus directly on the maximum unbraced length at which the flexural resistance is equal to M_{max} . The use of these equivalent procedures is recommended for prismatic unbraced lengths when C_b values greater than 1.0 are utilized in the design.

For compact-web and noncompact-web I-section members, the torsional restraint provided by the bridge deck may provide a significant enhancement to the elastic LTB resistance, or more properly stated, the elastic lateral distortional buckling resistance of the members. Assuming that the member is adequately braced at the cross-frame locations, this influence may be considered for constant web depth members by writing the elastic lateral distortional buckling moment of the torsionally restrained member as (Taylor and Ojalvo, 1966) (Yura, 2001):

$$M_{eLDB} = C_b \sqrt{(M_e)^2 + \frac{\beta_{sec} EI_{eff}}{C_T}} \quad (\text{CA6.3.3.2-1})$$

in which:

β_{sec} = effective continuous torsional bracing stiffness provided by the combination of restraint from the bridge deck plus the distortional stiffness of the I-section web (kip-in./rad)

$$= 3.3 \frac{E I_w^3}{D^{12}} \quad (\text{CA6.3.3.2-2})$$

I_{eff} = effective moment of inertia about the vertical centroidal axis of the girder (in.⁴)

$$= I_{yc} + \frac{D - D_c}{D_c} I_{yt} \quad (\text{CA6.3.3.2-3})$$

where:

C_b = moment-gradient modifier, calculated as specified in Article 6.10.8.2.3b

C_T = 1.2 for top-flange loading

D_c = depth of the web in compression in the elastic range (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.

I_{yc} = moment of inertia of the compression flange of the steel section about the vertical axis in the plane of the web (in.⁴)

I_{yt} = moment of inertia of the tension flange of the steel section about the vertical axis in the plane of the web (in.⁴)

M_e = elastic LTB moment $F_e S_{xc}$ considering the direction of bending associated with M_u (kip-in.)

F_e = elastic LTB stress given by Eq. A6.3.3.2-1 (ksi)

S_{xc} = elastic section modulus about the major axis of the section to the compression flange (in.³)

M_{yc} = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in)

The stiffness of the deck in resisting the torsional rotation of the girder top flange tends to be relatively large compared to the distortional stiffness of the web given by Eq. CA6.3.3.2-2 for all practical girder web and bridge deck thicknesses. Therefore, the deck is assumed to be rigid relative to the distortional stiffness of the web in restraining the top flange torsional rotation. Eq. CA6.3.3.2-3 was developed considering noncomposite I-section members. If I_{yt} is taken equal to I_{yc} , which is considered to be a conservative approximation since the bridge deck restrains the top flange against lateral bending, the elastic lateral distortional buckling stress of the bottom compression flange of a composite unbraced length may be approximated as:

$$F_{e\text{ LDB}} = C_b \sqrt{(F_e)^2 + \frac{E^2 t_{fc}^3 b_{fc}^3 t_w^3}{52 D_c S_{xc}^2}} \quad (\text{CA6.3.3.2-4})$$

This stress may be employed in place of F_e in Eq. A6.3.3.1-3 to recognize the benefits of the torsional

A6.3.3.3—LTB Parameters for Nonprismatic Unbraced Lengths

Moment-gradient effects should be considered in the calculation of the elastic LTB load ratio, γ_e , and the moment-gradient modifier, C_b , in Eq. A6.3.3.1-2 shall be taken as:

$$C_b = 1.0 \quad (\text{A6.3.3.3-1})$$

The elastic LTB stress, F_e , shall be calculated as:

$$F_e = \gamma_e f_{bu} \quad (\text{A6.3.3.3-2})$$

where $f_{bu} = M_u/S_{xc}$ is calculated at the location where $M_u/R_{pc}M_{yc}$ is maximum, and γ_e is calculated using one of the methods specified in Article D6.6, as applicable.

The radius of gyration for LTB, r_t , at the governing cross-section shall be taken as:

$$r_t = \frac{L_b F_e}{1.95 E} \sqrt{\frac{J}{S_{xc} h} + \sqrt{\left(\frac{J}{S_{xc} h}\right)^2 + 6.76 \left(\frac{F_e}{E}\right)^2}} \quad (\text{A6.3.3.3-3})$$

where:

S_{xc} = elastic section modulus about the major axis of the section to the compression flange (in.³)

The ratios of the lateral moments of inertia, I_{y1}/I_{y2} and I_{yb1}/I_{yb2} , of the adjacent flanges of each section at cross-section transitions within the unbraced length under consideration should be equal to or larger than 0.5, where:

I_{yb1} = lateral moment of inertia of the bottom flange of the steel section located closer to the brace point with the smaller magnitude of moment, taken about the vertical axis in the plane of the web (in.⁴)

restraint from the bridge deck and the distortional stiffness of the I-section web. For members with a section transition within the unbraced length under consideration, the last term of Eq. CA6.3.3.2-4 may be calculated conservatively as the smallest value obtained using the different section dimensions and properties along the unbraced length under consideration.

Eq. CA6.3.3.2-4 may be employed conservatively to account for the torsional restraint from the bridge deck at the top flange of variable-web-depth I-girders by using

the smallest value of $\frac{t_{fc} b_{fc}^3 t_w^3}{D_c S_{xc}^2}$ for the cross-sections along the unbraced length under consideration.

CA6.3.3.3

Article A6.3.3.3 addresses the extension of the elastic LTB calculation procedures contained in Article A6.3.3.2 to the handling of LTB in general nonprismatic unbraced lengths of compact and noncompact-web section members. This extension is grounded in the approach documented in AISC Design Guide 25 (White et al., 2021a), but is configured in the form of an “equivalent r_t ” given by Eq. A6.3.3.3-3 that allows the direct use of Eqs. A6.3.3.1-1 through A6.3.3.1-3 for the calculations. The equivalent r_t is calculated given the elastic buckling load multiplier, γ_e , which is the amount by which the calculated design moments would need to be scaled to reach the theoretical elastic LTB load level, illustrated in Figure CA6.3.3.3-1.

Figure CA6.3.3.3-1—Scaling of the Design Moment at the Governing Cross-Section by the Elastic LTB Load Ratio, γ_e , to Reach the Theoretical Elastic LTB Load Level

- I_{yb2} = lateral moment of inertia of the bottom flange of the steel section located closer to the brace point with the larger magnitude of moment, taken about the vertical axis in the plane of the web (in.⁴)
- I_{yt1} = lateral moment of inertia of the top flange of the steel section located closer to the brace point with the smaller magnitude of moment, taken about the vertical axis in the plane of the web (in.⁴)
- I_{yt2} = lateral moment of inertia of the top flange of the steel section located closer to the brace point with the larger magnitude of moment, taken about the vertical axis in the plane of the web (in.⁴)

Where a cross-section transition within the unbraced length occurs at a bolted field splice, the thickness of the splice plates should be included in the calculation of I_{yt1} and I_{yb1} ; the thickness of any fillers should not be included. In calculating the nominal LTB resistance of this unbraced length according to the provisions specified herein, the location of the transition shall be taken at the center of the splice and the contribution of the splice plates to the girder section properties shall be ignored.

For unbraced lengths of constant web depth members containing a single cross-section transition to a smaller section at a distance less than or equal to 20 percent of the unbraced length from the brace point with the smaller magnitude of the moment, and where the larger magnitude of the moment occurs within the section with the largest resistance, and where I_{yt1}/I_{yt2} and I_{yb1}/I_{yb2} of the adjacent flanges of each section at the transition is greater than or equal to 0.5, the LTB resistance, M_{nc} , may be determined assuming the member is prismatic using the parameters calculated as specified in Article A6.3.3.2; that is, assuming that the transition does not exist and that the flanges of the section closer to the brace point with the larger magnitude of moment are extended to the brace point with the smaller magnitude of moment. The moment-gradient modifier, C_b , from Article 6.10.8.2.3b should be calculated and applied, and also L_b may be modified by an effective length factor. Where the cross-section transition in this case occurs at a bolted field splice, I_{yt1} and I_{yb1} should be calculated as specified above, and the splice plates on the flange subject to compression should extend from the center of the splice at least 40 percent of the distance from the center of the splice to the brace point with the smaller magnitude of the moment.

Figure CA6.3.3.3-1 (cont.)—Scaling of the Design Moment at the Governing Cross-Section by the Elastic LTB Load Ratio, γ_e , to Reach the Theoretical Elastic LTB Load Level

For cases where the elastic LTB resistance is calculated directly from an elastic eigenvalue buckling analysis, γ_e is the smallest, or controlling, eigenvalue obtained from the buckling solution. The buckling stress, F_e , is the value of the elastic buckling stress at the governing cross-section, defined as the location where $M_u/R_{pc}M_{yc}$ is maximum. This aspect of the calculations is discussed further in Article CA6.3.3.1. Procedures for estimating γ_e are provided in Article D6.6.

It should be noted that in the limit that J is taken equal to zero, Eq. A6.3.3.3-3 reduces to Eq. 6.10.8.2.3c-3.

A6.4—FLEXURAL RESISTANCE BASED ON TENSION-FLANGE YIELDING

CA6.4

The nominal flexural resistance based on tension flange yielding shall be taken as:

$$M_{nt} = R_{pt} M_{yt} \quad (\text{A6.4-1})$$

where:

M_{yt} = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.)

R_{pt} = web plastification factor for tension-flange yielding determined as specified in Article A6.2.1 or Article A6.2.2, as applicable

Eq. A6.4-1 implements a linear transition in the flexural resistance between M_p and M_{yr} as a function of $2D_c/t_w$ for monosymmetric sections with a larger tension flange and for composite sections in negative flexure where first yielding occurs in the top flange or in the longitudinal reinforcing steel. In the limit that $2D_c/t_w$ approaches the noncompact web limit given by Eq. A6.2.2-3, Eq. A6.4-1 reduces to the tension-flange yielding limit specified in Article 6.10.8.3.

For sections in which $M_{jt} > M_{yc}$, Eq. A6.4-1 does not control and need not be checked.

This page intentionally left blank.

APPENDIX B6—MOMENT REDISTRIBUTION FROM INTERIOR-PIER I-SECTIONS IN STRAIGHT CONTINUOUS-SPAN BRIDGES

B6.1—GENERAL

This Article shall apply for the calculation of redistribution moments from the interior-pier sections of continuous-span I-section flexural members at the service and/or strength limit states. These provisions shall apply only for I-section members that satisfy the requirements of Article B6.2.

CB6.1

These optional provisions provide a simple rational approach for calculating the moment redistribution from interior-pier sections due to the effects of yielding. This approach utilizes elastic moment envelopes and does not require the direct use of any inelastic analysis methods. The restrictions of Article B6.2 ensure significant ductility and robustness at the interior-pier sections.

In conventional elastic analysis and design, moment and shear envelopes are typically determined by elastic analysis with no redistribution due to the effects of yielding considered. The sections are dimensioned for a resistance equal to or greater than that required by the envelopes. Designs to meet these requirements often involve the addition of cover plates to rolled beams, which introduces details that often have low fatigue resistance, or the introduction of multiple flange transitions in welded beams, which can result in additional fabrication costs. Where appropriate, the use of these provisions to account for the redistribution of moments makes it possible to eliminate such details by using prismatic sections along the entire length of the bridge or between field splices. This practice can improve overall fatigue resistance and provide significant fabrication economies.

Development of these provisions is documented in several comprehensive reports (Barker et al., 1997) (Schilling et al., 1997) (White et al., 1997) and in a summary paper by Barth et al. (2004), which give extensive references to other supporting research. These provisions account for the fact that the compression flange slenderness, $b_{fc}/2t_{fc}$, and the cross-section aspect ratio, D/b_{fc} , are the predominant factors that influence the moment-rotation behavior at adequately braced interior-pier sections. The provisions apply to sections with compact, noncompact, or slender webs.

B6.2—SCOPE

Moment redistribution shall be applied only in straight continuous-span I-section members whose support lines are not skewed more than 10 degrees from normal and along which there are no discontinuous cross-frames. Sections may be either composite or noncomposite in positive or negative flexure.

Cross-sections throughout the unbraced lengths immediately adjacent to interior-pier sections from which moments are redistributed shall have a specified minimum yield strength not exceeding 70.0 ksi. Holes shall not be placed within the tension flange over a distance of two times the web depth on either side of the interior-pier sections from which moments are redistributed. All other sections having tension flange holes shall satisfy the requirements of Article 6.10.1.8 after the moments are redistributed.

CB6.2

The subject procedures have been developed predominantly in the context of straight nonskewed bridge superstructures without discontinuous cross-frames. Therefore, their use is restricted to bridges that do not deviate significantly from these idealized conditions.

The development of these provisions focused on nonhybrid and hybrid girders with specified minimum yield strengths up to and including 70.0 ksi. Therefore, use of these provisions with larger yield strengths is not permitted. The influence of tension-flange holes on potential net section fracture at cross-sections experiencing significant inelastic strains is not well-known. Therefore, tension flange holes are not allowed over a distance of two times the web depth, D , on either side of the interior-pier sections from which moments are

Moments shall be redistributed only at interior-pier sections for which the cross-sections throughout the unbraced lengths immediately adjacent to those sections satisfy the requirements of Articles B6.2.1 through B6.2.6. If the refined method of Article B6.6 is used for calculation of the redistribution moments, all interior-pier sections are not required to satisfy these requirements; however, moments shall not be redistributed from sections that do not satisfy these requirements. Such sections instead shall satisfy the provisions of Articles 6.10.4.2, 6.10.8.1 or Article A6.1, as applicable, after redistribution. If the provisions of Articles B6.3 or B6.4 are utilized to calculate interior-pier redistribution moments, the unbraced lengths immediately adjacent to all interior-pier sections shall satisfy the requirements of Articles B6.2.1 through B6.2.6.

B6.2.1—Web Proportions

The web within the unbraced length under consideration shall be proportioned such that:

$$\frac{D}{t_w} \leq 150 \quad (\text{B6.2.1-1})$$

$$\frac{2D_c}{t_w} \leq 6.8 \sqrt{\frac{E}{F_{yc}}} \quad (\text{B6.2.1-2})$$

and:

$$D_{cp} \leq 0.75D \quad (\text{B6.2.1-3})$$

where:

D_c = depth of the web in compression in the elastic range (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.

D_{cp} = depth of the web in compression at the plastic moment, determined as specified in Article D6.3.2 (in.)

B6.2.2—Compression Flange Proportions

The compression flange within the unbraced length under consideration shall be proportioned such that:

$$\frac{b_{fc}}{2t_{fc}} \leq 0.38 \sqrt{\frac{E}{F_{yc}}} \quad (\text{B6.2.2-1})$$

and:

$$b_{fc} \geq \frac{D}{4.25} \quad (\text{B6.2.2-2})$$

redistributed. The distance $2D$ is an approximate upper bound for the length of the zone of primary inelastic response at these pier sections.

Unless a direct analysis is conducted by the Refined Method outlined in Article B6.6, all the interior-pier sections of a continuous-span member are required to satisfy the requirements of Articles B6.2.1 through B6.2.6 in order to redistribute the pier moments. This is because of the approximations involved in the simplified provisions of Articles B6.3 and B6.4 and the fact that inelastic redistribution moments from one interior support generally produce some nonzero redistribution moments at all of the interior supports.

CB6.2.1

Eq. B6.2.1-1 simply parallels Eq. 6.10.2.1.1-1 and is intended to eliminate the use of any benefits from longitudinal stiffening of the web at the pier section. The moment-rotation characteristics of sections with longitudinal web stiffeners have not been studied. Eqs. B6.2.1-2 and B6.2.1-3 are limits of the web slenderness and the depth of the web in compression considered in the development of these procedures.

CB6.2.2

The compression flange is required to satisfy the compactness limit within the unbraced lengths adjacent to the pier section. This limit is restated in Eq. B6.2.2-1. Slightly larger $b_{fc}/2t_{fc}$ values than this limit have been considered within the supporting research for these provisions. The compactness limit from Articles A6.3.2 and 6.10.8.2 is used for simplicity.

Eq. B6.2.2-2 represents the largest aspect ratio $D/b_{fc} = 4.25$ considered in the supporting research. As noted in Articles C6.10.2.2 and CB6.1, increasing values of this ratio have a negative influence on the strength and moment-rotation characteristics of I-section members.

B6.3—SERVICE LIMIT STATE

B6.3.1—General

Load combination Service II in Table 3.4.1-1 shall apply.

B6.3.2—Flexure

B6.3.2.1—Adjacent to Interior-Pier Sections

With the exception that the requirement of Eq. 6.10.4.2.2-4 shall be satisfied, the provisions of Article 6.10.4.2 shall not be checked within the regions extending in each adjacent span from interior-pier sections satisfying the requirements of Article B6.2 to the nearest flange transition or point of dead-load contraflexure, whichever is closest.

CB6.3.2.1

In checking permanent deflections under Load Combination Service II, local yielding is permitted at interior supports satisfying the requirements of Article B6.2. This results in redistribution. The permanent deflections are controlled by imposing the appropriate flange stress limits of Article 6.10.4.2 in each adjacent span at sections outside the nearest flange transition location or point of permanent-load contraflexure, whichever is closest to the interior support under consideration, after redistribution. The appropriate redistribution moments are to be added to the elastic moments due to the Service II loads prior to making these checks. The influence of the strength and ductility at the interior-pier sections is considered within the calculation of the redistribution moments. Therefore, the flange stress limits of Article 6.10.4.2 need not be checked within the regions extending into each adjacent span from the interior-pier section under consideration to the closest point cited above. The provisions of Appendix B6 are not intended to relax the requirement of Eq. 6.10.4.2.2-4. This requirement should be satisfied based on the elastic moments before redistribution.

Additional cambering to account for the small residual deformations associated with redistribution of interior-pier section moments is not recommended. A full-scale bridge designed to permit redistribution of negative moments sustained only very small permanent deflections when tested under the overload condition (Roeder and Eltvik, 1985).

B6.3.2.2—At All Other Locations

Sections at all other locations shall satisfy the provisions of Article 6.10.4.2, as applicable, after redistribution. For composite sections in positive flexure, the redistribution moments shall be applied to the long-term composite section when computing flexural stresses in the steel section. For computing longitudinal flexural stresses in the concrete deck due to the redistribution moments, the provisions of Article 6.10.1.1.1d shall apply.

The redistribution moments shall be calculated according to the provisions specified in Article B6.3.3 and shall be added to the elastic moments due to the Service II loads.

CB6.3.2.2

The redistribution moments are in effect permanent moments that remain in the structure. The corresponding locked-in redistribution stresses in composite sections tend to decrease with time as a result of creep in the concrete. However, these redistribution stresses may be continually renewed by subsequent passages of similar loadings. Therefore, the flexural stresses in the steel section due to these moments are to be conservatively calculated based on the long-term composite section.

B6.3.3—Redistribution Moments**B6.3.3.1—At Interior-Pier Sections**

At each interior-pier section where the flexural stresses are not checked as permitted in Article B6.3.2.1, the redistribution moment for the Service II loads shall be taken as:

$$M_{rd} = |M_e| - M_{pe} \quad (\text{B6.3.3.1-1})$$

in which:

$$0 \leq M_{rd} \leq 0.2|M_e| \quad (\text{B6.3.3.1-2})$$

where:

M_{pe} = negative-flexure effective plastic moment for the service limit state, determined as specified in Article B6.5 (kip-in.)

M_e = critical elastic moment envelope value at the interior-pier section due to the Service II loads (kip-in.)

B6.3.3.2—At All Other Locations

The redistribution-moment diagram for the Service II load combination shall be determined by connecting with straight lines the redistribution moments at adjacent interior-pier sections. The lines shall be extended to any points of zero redistribution moment at adjacent supports, including at the abutments.

CB6.3.3.1

Eqs. B6.3.3.1-1, B6.4.2.1-1 and B6.4.2.1-2 are based on concepts from shakedown analysis of continuous-span girders under repeated application of moving loads (ASCE, 1971) (Schilling et al., 1997) using an effective plastic moment that accounts for the interior-pier section moment-rotation characteristics. Shakedown is the appropriate limit state related to moment redistribution in bridges (Galambos et al., 1993).

At the service limit state, the effective plastic moment in Eq. B6.3.3.1-1 is based on an estimated upper-bound plastic rotation of 0.009 radians at the pier sections, determined by direct inelastic analysis of various trial designs (Schilling, 1986). Flange lateral bending effects are not considered in Eq. B6.3.3.1-1 since due to the restrictions of Article B6.2, the flange lateral bending effects at the interior supports under the Service II Load Combination are taken to be negligible. The refinement of these calculations by consideration of flange lateral bending effects is considered unjustified.

Eq. B6.3.3.1-2 is intended to prevent the use of an interior-pier section that is so small that it could potentially violate the assumed upper-bound inelastic rotation of 0.009 radians under Service II conditions. Note that if the upper limit of Eq. B6.3.3.1-2 is violated, a new interior-pier section must be selected that will ensure that this limit is satisfied.

CB6.3.3.2

Figure CB6.3.3.2-1 illustrates a typical redistribution moment diagram for a three-span continuous member for which the redistribution moments are greater than zero at both interior-pier sections. After the live loads are removed, the redistribution moments are held in equilibrium by the support reactions. Therefore, the redistribution moments must vary linearly between the supports.

Figure CB6.3.3.2-1—Typical Redistribution Moment Diagram

B6.4—STRENGTH LIMIT STATE**B6.4.1—Flexural Resistance****B6.4.1.1—Adjacent to Interior-Pier Sections**

The flexural resistances of sections within the unbraced lengths immediately adjacent to interior-pier sections satisfying the requirements of Article B6.2 shall not be checked.

B6.4.1.2—At All Other Locations

Sections at all other locations shall satisfy the provisions of Articles 6.10.7, 6.10.8.1, or A6.1, as applicable, after redistribution. For composite sections in positive flexure, the redistribution moments shall be applied to the long-term composite section when computing flexural stresses in the steel section. For computing longitudinal flexural stresses in the concrete deck due to the redistribution moments, the provisions of Article 6.10.1.1.1d shall apply.

The redistribution moments shall be calculated using the provisions of Article B6.4.2 and shall be added to the elastic moments due to the factored loads at the strength limit state.

B6.4.2—Redistribution Moments**B6.4.2.1—At Interior-Pier Sections**

At each interior-pier section where the flexural resistances are not checked as permitted in Article B6.4.1.1, the redistribution moment at the strength limit state shall be taken as the larger of:

$$M_{rd} = |M_e| + \frac{1}{3} f_t S_{xc} - \phi_f M_{pe} \quad (\text{B6.4.2.1-1})$$

or:

$$M_{rd} = |M_e| + \frac{1}{3} f_t S_{xt} - \phi_f M_{pe} \quad (\text{B6.4.2.1-2})$$

in which:

$$0 \leq M_{rd} \leq 0.2 |M_e| \quad (\text{B6.4.2.1-3})$$

where:

f_t = lateral bending stress in the flange under consideration at the interior-pier section (ksi).

CB6.4.1.1

Yielding is permitted at interior supports at the strength limit state, and results in redistribution of moments. The influence of the strength and ductility at the interior-pier sections is considered within the calculation of the redistribution moments. Therefore, the flexural resistances of sections within the unbraced lengths immediately adjacent to interior-pier sections from which moments are redistributed need not be checked.

CB6.4.1.2

Regions outside of unbraced lengths immediately adjacent to interior-pier sections from which moments are redistributed are designed in the same fashion as when the procedures of this Article are not applied, with the exception that the appropriate redistribution moments are to be added to the elastic moments due to the factored loads at the strength limit state prior to making the design checks.

CB6.4.2.1

At the strength limit state, the effective plastic moment in Eqs. B6.4.2.1-1 and B6.4.2.1-2 is based on an estimated upper-bound plastic rotation of 0.03 radians at the pier sections, determined by direct inelastic analysis of various trial designs (Schilling, 1986).

Flange lateral bending effects are conservatively included in Eqs. B6.4.2.1-1 and B6.4.2.1-2 to account for the reduction in the flexural resistance of the interior-pier section at the strength limit state due to these effects. The inclusion of f_t in these equations is intended primarily to address the design for wind loads. Eq. B6.4.2.1-3 is intended to prevent the use of an interior-pier section that is so small that it could potentially violate the assumed upper-bound inelastic rotation of 0.03 radians at the strength limit state. Note that if the upper limit of Eq. B6.4.2.1-3 is violated, a new interior-pier section must be selected that will ensure that this limit is satisfied.

A form of Eqs. B6.4.2.1-1 and B6.4.2.1-2 was proposed in the original research by Barker et al. (1997) that included a resistance factor for shakedown of $\phi_{sd} = 1.1$. The resistance factor of $\phi_{sd} = 1.1$ is justified for this limit state because the shakedown loading is

- For continuously braced tension or compression flanges, f_t shall be taken as zero.
- ϕ_f = resistance factor for flexure, specified in Article 6.5.4.2
- M_{pe} = negative-flexure effective plastic moment for the strength limit state, determined as specified in Article B6.5 (kip-in.)
- M_e = critical elastic moment envelope value at the interior-pier section due to the factored loads (kip-in.)
- M_{yc} = yield moment with respect to the compression flange, determined as specified in Article D6.2 (kip-in.)
- M_{yt} = yield moment with respect to the tension flange, determined as specified in Article D6.2 (kip-in.)
- S_{xc} = elastic section modulus about the major axis of the section to the compression flange, taken as M_{yc}/F_{yc} (in.³)
- S_{xt} = elastic section modulus about the major axis of the section to the tension flange, taken as M_{yt}/F_{yt} (in.³)

B6.4.2.2—At All Other Sections

The redistribution-moment diagram for the strength limit state shall be determined using the same procedure specified for the Service II load combination in Article B6.3.3.2.

B6.5—EFFECTIVE PLASTIC MOMENT

B6.5.1—Interior-Pier Sections with Enhanced Moment-Rotation Characteristics

For interior-pier sections satisfying the requirements of Article B6.2 and which contain:

- Transverse stiffeners spaced at $D/2$ or less over a minimum distance of $D/2$ on each side of the interior-pier section

or:

- Ultracompact webs that satisfy:

$$\frac{2D_{cp}}{t_w} \leq 2.3 \sqrt{\frac{E}{F_{yc}}} \quad (\text{B6.5.1-1})$$

where:

D_{cp} = depth of the web in compression at the plastic moment determined as specified in Article D6.3.2 (in.)

the effective plastic moment shall be taken as:

- For the service limit state:

$$M_{pe} = M_n \quad (\text{B6.5.1-2})$$

generally less than the maximum plastic resistance and because progressively increasing permanent deflections give ample warning of pending failure. The resistance factor for flexure ϕ_f of Article 6.5.4.2 is selected in these provisions to account for the fact that yielding within regions of positive flexure and the corresponding redistribution of positive bending moments to the interior-pier sections is not considered. Also, as discussed in Article C6.10.7.1.2, additional requirements are specified in continuous spans where significant yielding may occur prior to reaching the section resistances of compact sections in positive flexure.

CB6.4.2.2

Figure CB6.3.3.2-1 illustrates a typical redistribution moment diagram.

CB6.5.1

Tests have shown that members with interior-pier sections that satisfy either of the requirements of this Article, in addition to the requirements of Article B6.2, exhibit enhanced moment-rotation characteristics relative to members that satisfy only the requirements of Article B6.2 (White et al., 1997) (Barth et al., 2004). These additional requirements involve the use of:

- Transverse stiffeners close to the interior-pier section to help restrain the local buckling distortions of the web and compression flange within this region, or
- A web that is sufficiently stocky such that its distortions are reduced and the FLB distortions are highly restrained, termed an ultracompact web.

For noncompact web and slender web sections, the influence of the web slenderness on the effective plastic moment is captured through the maximum flexural resistance term, M_n , in Eqs. B6.5.1-2 and B6.5.1-3, and in Eqs. B6.5.2-1 and B6.5.2-2.

- For the strength limit state:

$$M_{pe} = \left(\begin{array}{l} 2.78 - 2.3 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \\ -0.35 \frac{D}{b_{fc}} + 0.39 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \frac{D}{b_{fc}} \end{array} \right) M_n \leq M_n \quad (\text{B6.5.1-3})$$

where:

M_n = nominal flexural resistance of the interior-pier section, taken as the smaller of $F_{nc}S_{xc}$ and $F_{nt}S_{xt}$, with F_{nc} and F_{nt} determined as specified in Article 6.10.8. For sections with compact or noncompact webs, M_n may be taken as the smaller of M_{nc} and M_{nt} , determined as specified in Appendix A6 (kip-in.).

B6.5.2—All Other Interior-Pier Sections

For interior-pier sections satisfying the requirements of Article B6.2, but not satisfying the requirements of Article B6.5.1, the effective plastic moment shall be taken as:

- For the service limit state:

$$M_{pe} = \left(\begin{array}{l} 2.90 - 2.3 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \\ -0.35 \frac{D}{b_{fc}} + 0.39 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \frac{D}{b_{fc}} \end{array} \right) M_n \leq M_n \quad (\text{B6.5.2-1})$$

- For the strength limit state:

$$M_{pe} = \left(\begin{array}{l} 2.63 - 2.3 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \\ -0.35 \frac{D}{b_{fc}} + 0.39 \frac{b_{fc}}{t_{fc}} \sqrt{\frac{F_{yc}}{E}} \frac{D}{b_{fc}} \end{array} \right) M_n \leq M_n \quad (\text{B6.5.2-2})$$

B6.6—REFINED METHOD

B6.6.1—General

Continuous-span I-section flexural members satisfying the requirements of Article B6.2 also may be proportioned based on a direct analysis. In this approach, the redistribution moments shall be determined by satisfying rotational continuity and specified inelastic moment-rotation relationships at selected interior-pier sections. Direct

CB6.5.2

Eqs. B6.5.2-1 and B6.5.2-2 are based on a lower-bound estimate of the moment-rotation characteristics of interior-pier sections that satisfy the limits of Article B6.2 (Barth et al., 2004). Cases with unbraced lengths smaller than the limit given by Eq. B6.2.4-1, significant torsional restraint from a composite deck, and/or compression flange slenderness values significantly smaller than the compact flange limit often exhibit significantly enhanced moment-rotation characteristics and corresponding larger effective plastic moments than the values obtained from these equations.

The web slenderness, $2D_c/t_w$ or $2D_{cp}/t_{ws}$, does not appear directly in Eqs. B6.5.2-1 and B6.5.2-2. For noncompact and slender web sections, the influence of the web slenderness on the effective plastic moment is captured through the maximum flexural resistance term, M_n .

CB6.6.1

The Engineer is also provided the option to use a refined method in which a direct shakedown analysis is conducted at the service and/or strength limit states. This analysis requires the simultaneous satisfaction of continuity and moment-rotation relationships at all interior-pier sections from which moments are

analysis may be employed at the service and/or strength limit states. The elastic moment envelope due to the factored loads shall be used in this analysis.

For the direct analysis, the redistribution moments shall be determined using the elastic stiffness properties of the short-term composite section assuming the concrete deck to be effective over the entire span length. For composite sections in positive flexure, the redistribution moments shall be applied to the long-term composite section when computing elastic flexural stresses in the steel section. For computing elastic longitudinal flexural stresses in the concrete deck due to the redistribution moments, the provisions of Article 6.10.1.1.1d shall apply.

Sections adjacent to interior piers from which moments are redistributed shall satisfy the requirements of Article B6.3.2.1 at the service limit state and Article B6.4.1.1 at the strength limit state. All other sections shall satisfy all applicable provisions of Articles 6.10.4.2, 6.10.7, 6.10.8.1, or A6.1 after a solution is found.

In applying direct analysis at the strength limit state, the ordinates of the nominal moment-rotation curves shall be multiplied by the resistance factor for flexure specified in Article 6.5.4.2. In applying direct analysis at the Service II limit state, the nominal moment-rotation curves shall be used.

redistributed. If software that handles this type of calculation along with the determination of the elastic moment envelopes does not exist, significant manual work is required in conducting the analysis calculations. The Engineer can gain some additional benefit when using direct analysis in that the restriction that all interior-pier sections within the member satisfy the requirements of Article B6.2.1 is relaxed. Also, the directly calculated inelastic rotations at the interior-pier sections will tend to be smaller than the upper-bound values on which the equations in Articles B6.3 through B6.5 are based.

The redistribution moments are to be computed using the stiffness properties of the short-term composite section because the redistribution moments are formed by short-term loads.

Although direct analysis methods can be formulated that account for the redistribution of moments from regions of positive flexure, there is typically no significant economic benefit associated with redistribution of positive bending moments. This is because, in most practical cases, the interior-pier sections have the highest elastic stresses. Also, the development of some inelastic rotations at the pier sections simply allows a continuous-span member to respond in a fashion involving only slightly less rotational restraint from the adjacent spans than if these sections remain elastic.

With the exception of the additional requirements of Article 6.10.7.1.2 for composite sections subjected to positive flexure within continuous spans in which the adjacent interior-pier sections do not satisfy Article B6.2, these Specifications generally neglect the influence of partial yielding prior to and associated with the development of member maximum flexural resistances. Therefore, the influence of partial yielding within regions of positive flexure on the redistribution of moments to the interior piers and on the calculated inelastic pier rotations is also to be neglected within the direct analysis approach. The unconservative attributes associated with neglecting positive-moment yielding prior to reaching the maximum flexural resistance within regions of positive flexure are offset by:

- the use of $\phi_f = 1.0$ rather than a shakedown resistance factor of $\phi_{sd} = 1.1$ as originally formulated by Barker et al. (1997) and discussed in Article CB6.4.2.1, and
- the lower-bound nature of the moment-rotation relationships utilized for the interior-pier sections.

Moment-rotation relationships have been proposed that account for yielding in positive flexure, such as in Barker et al. (1997). However, these relationships account in only a very simplistic fashion for the distributed yielding effects that tend to occur over a significant length due to the small moment gradients that typically exist within regions of positive flexure. Significantly greater accuracy can be achieved in the analysis for these effects by the use of

specified in Appendix A6. For load combinations that induce significant flange lateral bending stresses, the influence of flange lateral bending shall be considered by deducting the larger of $\frac{1}{3}f_r S_{xc}$ or $\frac{1}{3}f_r S_{xt}$ from the above values.

f_{ℓ} = lateral bending stress in the flange under consideration at the interior-pier section (ksi). For continuously braced tension or compression flanges, f_{ℓ} shall be taken as zero.

Other nominal moment-rotation relationships may be employed for interior-pier sections that satisfy the requirements of Article B6.2 provided that the relationships are developed considering all potential factors that influence the moment-rotation characteristics within the restrictions of those requirements.

Interior-pier sections not satisfying the requirements of Article B6.2 shall be assumed to remain elastic in the analysis, and shall satisfy the provisions of Articles 6.10.4.2, 6.10.8.1, or Article A6.1, as applicable, after a solution is found.

APPENDIX C6—BASIC STEPS FOR STEEL BRIDGE SUPERSTRUCTURES**C6.1—GENERAL**

This outline is intended to be a generic overview of the design process. It should not be regarded as fully complete, nor should it be used as a substitute for a working knowledge of the provisions of this Section.

C6.2—GENERAL CONSIDERATIONS

- A. Design Philosophy (1.3.1)
- B. Limit States (1.3.2)
- C. Design and Location Features (2.3) (2.5)

C6.3—SUPERSTRUCTURE DESIGN

- A. Develop General Section
 - 1. Roadway Width (Highway Specified)
 - 2. Span Arrangements (2.3.2) (2.5.4) (2.5.5) (2.6)
 - 3. Select Bridge Type—assumed to be I- or Box Girder
- B. Develop Typical Section
 - 1. I-girder
 - a. Composite (6.10.1.1) or Noncomposite (6.10.1.2)
 - b. Hybrid or Nonhybrid (6.10.1.3)
 - c. Variable Web Depth (6.10.1.4)
 - d. Cross-section Proportion Limits (6.10.2)
 - 2. Box Girder
 - a. Multiple Boxes or Single Box (6.11.1.1) (6.11.2.3)
 - b. Hybrid or Nonhybrid (6.10.1.3)
 - c. Variable Web Depth (6.10.1.4)
 - d. Cross-section Proportion Limits (6.11.2)
 - e. Bearings (6.11.1.2)
 - f. Orthotropic Deck (6.14.3)
- C. Design Conventionally Reinforced Concrete Deck
 - 1. Deck Slabs (4.6.2.1)
 - 2. Minimum Depth (9.7.1.1)
 - 3. Empirical Design (9.7.2)
 - 4. Traditional Design (9.7.3)
 - 5. Strip Method (4.6.2.1)
 - 6. Live Load Application (3.6.1.3.3) (4.6.2.1.4) (4.6.2.1.5)
 - 7. Distribution Reinforcement (9.7.3.2)
 - 8. Overhang Design (A13.4) (3.6.1.3.4)
 - 9. Minimum Negative Flexure Concrete Deck Reinforcement (6.10.1.7)
- D. Select Resistance Factors
 - 1. Strength Limit State (6.5.4.2)
- E. Select Load Modifiers
 - 1. Ductility (1.3.3)
 - 2. Redundancy (1.3.4)
 - 3. Operational Importance (1.3.5)
- F. Select Load Combinations and Load Factors (3.4.1)
 - 1. Strength Limit State (6.5.4.1) (6.10.6.1) (6.11.6.1)
 - 2. Service Limit State (6.10.4.2.1)
 - 3. Fatigue and Fracture Limit State (6.5.3)
- G. Calculate Live Load Force Effects
 - 1. Select Live Loads (3.6.1) and Number of Lanes (3.6.1.1.1)
 - 2. Multiple Presence (3.6.1.1.2)
 - 3. Dynamic Load Allowance (3.6.2)
 - 4. Distribution Factor for Moment (4.6.2.2.2)
 - a. Interior Beams with Concrete Decks (4.6.2.2.2b)

- b. Exterior Beams (4.6.2.2.2d)
 - c. Skewed Bridges (4.6.2.2.2e)
 - 5. Distribution Factor for Shear (4.6.2.2.3)
 - a. Interior Beams (4.6.2.2.3a)
 - b. Exterior Beams (4.6.2.2.3b)
 - c. Skewed Bridges (4.6.2.2.3c)

APPENDIX D6—FUNDAMENTAL CALCULATIONS FOR FLEXURAL MEMBERS

D6.1—PLASTIC MOMENT

The plastic moment, M_p , shall be calculated as the moment of the plastic forces about the plastic neutral axis. Plastic forces in steel portions of a cross-section shall be calculated using the yield strengths of the flanges, the web, and reinforcing steel, as appropriate. Plastic forces in concrete portions of the cross-section that are in compression may be based on a rectangular stress block with the magnitude of the compressive stress equal to $0.85f'_c$. Concrete in tension shall be neglected.

The position of the plastic neutral axis shall be determined by the equilibrium condition that there is no net axial force.

The plastic moment of a composite section in positive flexure can be determined by:

- calculating the element forces and using them to determine whether the plastic neutral axis is in the web, top flange or concrete deck;
- calculating the location of the plastic neutral axis within the element determined in the first step; and
- calculating M_p . Equations for the various potential locations of the plastic neutral axis (PNA) are given in Table D6.1-1.

The forces in the longitudinal reinforcement may be conservatively neglected. To do this, set P_{rb} and P_r equal to zero in the equations in Table D6.1-1.

The plastic moment of a composite section in negative flexure can be calculated by an analogous procedure. Equations for the two cases most likely to occur in practice are given in Table D6.1-2.

The plastic moment of a noncomposite section may be calculated by eliminating the terms pertaining to the concrete deck and longitudinal reinforcement from the equations in Tables D6.1-1 and D6.1-2 for composite sections.

In the equations for M_p given in Tables D6.1-1 and D6.1-2, d is the distance from an element force to the plastic neutral axis. Element forces act at (a) mid-thickness for the flanges and the concrete deck, (b) mid-depth of the web, and (c) center of reinforcement. All element forces, dimensions, and distances should be taken as positive. The condition should be checked in the order listed in Tables D6.1-1 and D6.1-2.

Table D6.1-1—Calculation of $\bar{Y}$ and M_p for Sections in Positive Flexure

Case	PNA	Condition	$\bar{Y}$ and M_p
I	In Web	$P_t + P_w \geq P_c + P_s + P_{rb} + P_{rt}$	$\bar{Y} = \left(\frac{D}{2} \right) \left[\frac{P_t - P_c - P_s - P_{rt} - P_{rb}}{P_w} + 1 \right]$ $M_p = \frac{P_w}{2D} \left[\bar{Y}^2 + (D - \bar{Y})^2 \right] + [P_s d_s + P_{rt} d_{rt} + P_{rb} d_{rb} + P_c d_c + P_t d_t]$
II	In Top Flange	$P_t + P_w + P_c \geq P_s + P_{rb} + P_{rt}$	$\bar{Y} = \left(\frac{t_c}{2} \right) \left[\frac{P_w + P_t - P_s - P_{rt} - P_{rb}}{P_c} + 1 \right]$ $M_p = \frac{P_c}{2t_c} \left[\bar{Y}^2 + (t_c - \bar{Y})^2 \right] + [P_s d_s + P_{rt} d_{rt} + P_{rb} d_{rb} + P_w d_w + P_t d_t]$
III	Concrete Deck, Below P_{rb}	$P_t + P_w + P_c \geq \left(\frac{c_{rb}}{t_s} \right) P_s + P_{rb} + P_{rt}$	$\bar{Y} = (t_s) \left[\frac{P_c + P_w + P_t - P_{rt} - P_{rb}}{P_s} \right]$ $M_p = \left(\frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rt} d_{rt} + P_{rb} d_{rb} + P_c d_c + P_w d_w + P_t d_t]$
IV	Concrete Deck, at P_{rb}	$P_t + P_w + P_c + P_{rb} \geq \left(\frac{c_{rb}}{t_s} \right) P_s + P_{rt}$	$\bar{Y} = c_{rb}$ $M_p = \left(\frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rt} d_{rt} + P_c d_c + P_w d_w + P_t d_t]$
V	Concrete Deck, Above P_{rb} Below P_{rt}	$P_t + P_w + P_c + P_{rb} \geq \left(\frac{c_{rt}}{t_s} \right) P_s + P_{rt}$	$\bar{Y} = (t_s) \left[\frac{P_{rb} + P_c + P_w + P_t - P_{rt}}{P_s} \right]$ $M_p = \left(\frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rt} d_{rt} + P_{rb} d_{rb} + P_c d_c + P_w d_w + P_t d_t]$
VI	Concrete Deck, at P_{rt}	$P_t + P_w + P_c + P_{rb} + P_{rt} \geq \left(\frac{c_{rt}}{t_s} \right) P_s$	$\bar{Y} = c_{rt}$ $M_p = \left(\frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rb} d_{rb} + P_c d_c + P_w d_w + P_t d_t]$
VII	Concrete Deck, Above P_{rt}	$P_t + P_w + P_c + P_{rb} + P_{rt} < \left(\frac{c_{rt}}{t_s} \right) P_s$	$\bar{Y} = (t_s) \left[\frac{P_{rb} + P_c + P_w + P_t + P_{rt}}{P_s} \right]$ $M_p = \left(\frac{\bar{Y}^2 P_s}{2t_s} \right) + [P_{rt} d_{rt} + P_{rb} d_{rb} + P_c d_c + P_w d_w + P_t d_t]$

Table D6.1-2—Calculation of $\bar{Y}$ and M_p for Sections in Negative Flexure

Case	PNA	Condition	$\bar{Y}$ and M_p
I	In Web	$P_c + P_w \geq P_t + P_{rb} + P_{rt}$	$\bar{Y} = \left(\frac{D}{2} \right) \left[\frac{P_c - P_t - P_{rt} - P_{rb}}{P_w} + 1 \right]$ $M_p = \frac{P_w}{2D} \left[\bar{Y}^2 + (D - \bar{Y})^2 \right] + [P_{rt}d_{rt} + P_{rb}d_{rb} + P_t d_t + P_c d_c]$
II	In Top Flange	$P_c + P_w + P_t \geq P_{rb} + P_{rt}$	$\bar{Y} = \left(\frac{t_t}{2} \right) \left[\frac{P_w + P_c - P_{rt} - P_{rb}}{P_t} + 1 \right]$ $M_p = \frac{P_t}{2t_t} \left[\bar{Y}^2 + (t_t - \bar{Y})^2 \right] + [P_{rt}d_{rt} + P_{rb}d_{rb} + P_w d_w + P_c d_c]$

in which:

$$P_{rt} = F_{yr} A_{rt}$$

$$P_s = 0.85 f'_c b_s t_s$$

$$P_{rb} = F_{yb} A_{rb}$$

$$P_c = F_{yc} b_c t_c$$

$$P_w = F_{yw} D t_w$$

$$P_t = F_{yt} b_t t_t$$

where:

M_p = plastic moment (kip-in.)
 P_t = plastic force in the tension flange used to compute the plastic moment (kip)
 P_w = plastic force in the web used to compute the plastic moment (kip)
 P_c = plastic force in the compression flange used to compute the plastic moment (kip)
 P_s = plastic compressive force in the concrete deck used to compute the plastic moment (kip)
 P_{rb} = plastic force in the bottom layer of longitudinal deck reinforcement used to compute the plastic moment (kip)

- P_{rt} = plastic force in the top layer of longitudinal deck reinforcement used to compute the plastic moment (kip)
- $\bar{y}$ = distance from the plastic neutral axis to the top of the element where the plastic neutral axis is located (in.)
- d_s = distance from the centerline of the closest plate longitudinal stiffener or from the gauge line of the closest angle longitudinal stiffener to the inner surface or leg of the compression flange element (in.); distance from the plastic neutral axis to the mid-thickness of the concrete deck used to compute the plastic moment (in.)
- d_{rt} = distance from the plastic neutral axis to the centerline of the top layer of longitudinal concrete deck reinforcement used to compute the plastic moment (in.)
- d_{rb} = distance from the plastic neutral axis to the centerline of the bottom layer of longitudinal concrete deck reinforcement used to compute the plastic moment (in.)
- d_c = depth of a column in a rigid frame (in.); distance from the plastic neutral axis to the mid-thickness of the compression flange used to compute the plastic moment (in.)
- d_t = distance from the plastic neutral axis to the mid-thickness of the tension flange used to compute the plastic moment (in.)
- d_w = distance from the plastic neutral axis to the mid-depth of the web used to compute the plastic moment (in.)
- c_{rb} = distance from the top of the concrete deck to the centerline of the bottom layer of longitudinal concrete deck reinforcement (in.)
- c_{rt} = distance from the top of the concrete deck to the centerline of the top layer of longitudinal concrete deck reinforcement (in.)
- b_c = full width of the compression flange (in.)
- b_t = full width of the tension flange (in.)
- A_{rt} = area of the top layer of longitudinal reinforcement within the effective concrete deck width (in.²)
- A_{rb} = area of the bottom layer of longitudinal reinforcement within the effective concrete deck width (in.²)
- F_{yrt} = specified minimum yield strength of the top layer of longitudinal concrete deck reinforcement (ksi)
- F_{yrb} = specified minimum yield strength of the bottom layer of longitudinal concrete deck reinforcement (ksi)

D6.2—YIELD MOMENT

D6.2.1—Noncomposite Sections

The yield moment, M_y , of a noncomposite section shall be taken as the smaller of the moment required to cause nominal first yielding in the compression flange, M_{yc} , and the moment required to cause nominal first yielding in the tension flange, M_{yt} , at the strength limit state. Flange lateral bending in all types of sections and

web yielding in hybrid sections shall be disregarded in this calculation. Longitudinal stiffeners should be included in calculating the section properties of the member gross cross-section when determining the yield moment.

D6.2.2—Composite Sections in Positive Flexure

The yield moment of a composite section in positive flexure shall be taken as the sum of the moments applied separately to the steel and the short-term and long-term composite sections to cause nominal first yielding in either steel flange at the strength limit state. Flange lateral bending in all types of sections and web yielding in hybrid sections shall be disregarded in this calculation.

The yield moment of a composite section in positive flexure may be determined as follows:

- Calculate the moment M_{D1} caused by the factored permanent load applied before the concrete deck has hardened or is made composite. Apply this moment to the steel section.
- Calculate the moment M_{D2} caused by the remainder of the factored permanent load. Apply this moment to the long-term composite section.
- Calculate the additional moment M_{AD} that must be applied to the short-term composite section to cause nominal yielding in either steel flange.
- The yield moment is the sum of the total permanent load moment and the additional moment.

Symbolically, the procedure is:

- 1) Solve for M_{AD} from the equation:

$$F_y = \frac{M_{D1}}{S_{NC}} + \frac{M_{D2}}{S_{LT}} + \frac{M_{AD}}{S_{ST}} \quad (\text{D6.2.2-1})$$

- 2) Then calculate:

$$M_y = M_{D1} + M_{D2} + M_{AD} \quad (\text{D6.2.2-2})$$

where:

S_{NC} = noncomposite section modulus (in.³)
 S_{ST} = short-term composite section modulus (in.³)
 S_{LT} = long-term composite section modulus (in.³)

M_{D1} , M_{D2} ,
 & M_{AD} = moments due to the factored loads applied to the appropriate sections (kip-in.)

M_y shall be taken as the lesser value calculated for the compression flange, M_{yc} , or the tension flange, M_{yt} .

D6.2.3—Composite Sections in Negative Flexure

For composite sections in negative flexure, the procedure specified in Article D6.2.2 is followed, except that the composite section for both short-term and long-term moments shall consist of the steel section and the longitudinal reinforcement within the effective width of the concrete deck. Thus, S_{ST} and S_{LT} are the same value. Also, M_{yt} shall be taken with respect to either the tension flange or the longitudinal reinforcement, whichever yields first. For the calculation of M_{yt} with respect to the longitudinal reinforcement, M_{Dl} shall be taken equal to zero in Eqs. D6.2.2-1 and D6.2.2-2, and F_{yt} in Eq. D6.2.2-1 shall be taken equal to the specified minimum yield strength of the longitudinal reinforcement.

D6.2.4—Sections with Cover Plates

For sections containing flange cover plates, M_{yc} or M_{yt} shall be taken as the smallest value of moment associated with nominal first yielding based on the stress in either the flange under consideration or in any of the cover plates attached to that flange, whichever yields first. Flange lateral bending in all types of sections and web yielding in hybrid sections shall be disregarded in this calculation.

D6.3—DEPTH OF THE WEB IN COMPRESSION

D6.3.1—In the Elastic Range, D_c

For composite sections in positive flexure, the depth of the web in compression in the elastic range, D_c , shall be the depth over which the algebraic sum of the factored stresses in the steel, long-term composite and short-term composite sections from the dead and live loads, plus impact, is compressive.

In lieu of computing D_c at sections in positive flexure from stress diagrams, the following equation may be used:

$$D_c = \left(\frac{-f_c}{|f_c| + f_t} \right) d - t_{fc} \geq 0 \quad (\text{D6.3.1-1})$$

Figure D6.3.1-1—Computation of D_c at Sections in Positive Flexure

where:

- d = depth of the steel section (in.)
- f_c = sum of the factored compression-flange stresses caused by the different loads, i.e., DC1, the permanent load acting on the noncomposite section; DC2, the permanent load acting on the

CD6.3.1

At sections in positive flexure, the value of D_c of the composite section will increase with increasing span length because of the increasing dead-to-live load ratio. Therefore, in general it is important to recognize the effect of the dead-load stress on the location of the neutral axis of the composite section in regions of positive flexure.

According to these Specifications, for composite sections in positive flexure, Eq. D6.3.1-1 only need be employed for checking web bend-buckling at the service limit state and for computing the R_b factor at the strength limit state for sections in which web longitudinal stiffeners are required based on Article 6.10.2.1.1. Eq. D6.3.1-1 is never needed for composite sections in positive flexure when the web satisfies the requirement of Article 6.10.2.1.1 such that longitudinal stiffeners are not required. Articles C6.10.1.9.2, C6.10.1.10.2, and C6.10.4.2.2 discuss the rationale for these calculations, which introduce a dependency of the flexural resistance on the applied load whenever $R_b < 1$, and therefore, potentially complicate subsequent rating calculations for these section types. Article C6.10.1.9.1 explains why the calculation of D_c is not required for composite sections in positive flexure when the web satisfies Article 6.10.2.1.1.

For composite sections in negative flexure, the concrete deck is typically not considered to be effective in tension. Therefore, the distance between the neutral axis locations for the steel and composite sections is small in this case and the location of the neutral axis for the composite section is largely unaffected by the dead-load stress. Therefore, for the majority of situations, these Specifications specify the use of D_c computed simply for

long-term composite section; DW , the wearing surface load; and $LL+IM$; acting on their respective sections (ksi). f_c shall be taken as negative when the stress is in compression. Flange lateral bending shall be disregarded in this calculation.

f_i = the sum of the factored tension-flange stresses caused by the different loads (ksi). Flange lateral bending shall be disregarded in this calculation.

For composite sections in negative flexure, D_c shall be computed for the section consisting of the steel girder plus the longitudinal reinforcement with the exception of the following. For composite sections in negative flexure at the service limit state where the concrete deck is considered effective in tension for computing flexural stresses on the composite section due to Load Combination Service II, D_c shall be computed from Eq. D6.3.1-1.

D6.3.2—At Plastic Moment, D_{cp}

For composite sections in positive flexure, the depth of the web in compression at the plastic moment, D_{cp} , shall be taken as follows for cases from Table D6.1-1 where the plastic neutral axis is in the web:

$$D_{cp} = \frac{D}{2} \left(\frac{F_{yt} A_t - F_{yc} A_c - 0.85 f'_c A_s - F_{yrs} A_{rs}}{F_{yw} A_w} + 1 \right) \quad (\text{D6.3.2-1})$$

where:

A_c = area of the compression flange (in.²)
 A_{rs} = total area of the longitudinal reinforcement within the effective concrete deck width (in.²)
 A_s = area of the concrete deck (in.²)
 A_t = area of the tension flange (in.²)
 A_w = area of the web (in.²)
 D_{cp} = depth of the web in compression at the plastic moment (in.)
 F_{yrs} = specified minimum yield strength of the longitudinal reinforcement (ksi)

For all other composite sections in positive flexure, D_{cp} shall be taken equal to zero.

For composite sections in negative flexure, D_{cp} shall be taken as follows for cases from Table D6.1-2 where the plastic neutral axis is in the web:

$$D_{cp} = \frac{D}{2 A_w F_{yw}} [F_{yt} A_t + F_{yw} A_w + F_{yrs} A_{rs} - F_{yc} A_c] \quad (\text{D6.3.2-2})$$

For all other composite sections in negative flexure, D_{cp} shall be taken equal to D .

the section consisting of the steel girder plus the longitudinal reinforcement, without considering the algebraic sum of the stresses acting on the noncomposite and composite sections. This eliminates potential difficulties in subsequent load rating since the resulting D_c is independent of the applied loading, and therefore the flexural resistance in negative bending, which depends on D_c , does not depend on the applied load. The single exception is that if the concrete deck is assumed effective in tension in regions of negative flexure at the service limit state, as permitted for composite sections satisfying the requirements specified in Article 6.10.4.2.1, Eq. D6.3.1-1 must be used to compute D_c . For this case, in Figure D6.3.1-1, the stresses f_c and f_i should be switched, the signs shown in the stress diagram should be reversed, t_{fc} should be the thickness of the bottom flange, and D_c should instead extend from the neutral axis down to the top of the bottom flange.

For noncomposite sections where:

$$F_{yw}A_w \geq |F_{yc}A_c - F_{yt}A_t| \quad (\text{D6.3.2-3})$$

D_{cp} shall be taken as:

$$D_{cp} = \frac{D}{2A_w F_{yw}} [F_{yt}A_t + F_{yw}A_w - F_{yc}A_c] \quad (\text{D6.3.2-4})$$

For all other noncomposite sections, D_{cp} shall be taken equal to D .

D6.4—LTB EQUATIONS FOR $C_b > 1.0$, WITH EMPHASIS ON UNBRACED LENGTH REQUIREMENTS FOR DEVELOPMENT OF THE MAXIMUM FLEXURAL RESISTANCE

D6.4.1—By the Provisions of Article 6.10.8.2.3

For unbraced lengths in which the member is prismatic, the LTB resistance of the compression flange shall be taken as:

- If $L_b \leq L_p$, then:

$$F_{nc} = R_b R_h F_{yc} \quad (\text{D6.4.1-1})$$

- If $L_p < L_b \leq L_r$, then:

$$\begin{aligned} \circ \text{ If } L_b \leq L_p + \left(\frac{1 - \frac{1}{C_b}}{1 - \frac{F_{yr}}{R_h F_{yc}}} \right) (L_r - L_p), \text{ then:} \\ F_{nc} = R_b R_h F_{yc} \end{aligned} \quad (\text{D6.4.1-2})$$

- Otherwise:

$$F_{nc} = C_b \left[1 - \left(1 - \frac{F_{yr}}{R_h F_{yc}} \right) \left(\frac{L_b - L_p}{L_r - L_p} \right) \right] R_b R_h F_{yc} \leq R_b R_h F_{yc} \quad (\text{D6.4.1-3})$$

- If $L_b > L_r$, then:

$$\circ \text{ If } L_b \leq \pi r_t \sqrt{\frac{C_b E}{R_h F_{yc}}}, \text{ then:}$$

$$F_{nc} = R_b R_h F_{yc} \quad (\text{D6.4.1-4})$$

- Otherwise:

$$F_{nc} = R_b F_e \leq R_b R_h F_{yc} \quad (\text{D6.4.1-5})$$

CD6.4.1

For values of the moment-gradient modifier, C_b , greater than 1.0, the maximum LTB resistance F_{max} shown in Figure C6.10.8.2.1-1 may be reached at larger unbraced lengths. The provisions in this Article are equivalent to those in Articles 6.10.8.2.3, but allow the Engineer to focus on the conditions for which the LTB resistance is equal to $F_{max} = R_b R_h F_{yc}$ when the effects of moment gradient are included in determining the limits on L_b .

The largest unbraced length for which the LTB resistance of Article 6.10.8.2.3 is equal to the FLB or flange-flange local buckling resistance of Article 6.10.8.2.2 may be determined by substituting $F_{nc(FLB)}/R_b$ for $R_h F_{yc}$ in checking the L_b requirement for the use of Eq. D6.4.1-2 or D6.4.1-4 as applicable, where $F_{nc(FLB)}$ is the flange-flange local buckling resistance obtained from Article 6.10.8.2.2.

If $D_{ctw}/b_{fc} t_{fc}$ in Eq. 6.10.8.2.3b-3 is taken as a representative value of 2.0, F_{yc} is taken as 50 ksi, and $F_{yw} > 0.7 F_{yc}$, the LTB resistance of Article 6.10.8.2.3 is equal to F_{max} for $L_b < 22 b_{fc}$ when $C_b > 1.75$ and $L_b < 17 b_{fc}$ for $C_b > 1.3$. The Engineer should note that, even with relatively small values of C_b , the unbraced length requirements to achieve a flexural resistance of F_{max} are significantly larger than those associated with uniform major-axis bending and $C_b = 1$. Article C6.10.8.2.3b discusses the appropriate calculation of $C_b > 1$ for bridge design.

All terms in the above equations shall be taken as defined in Articles 6.10.8.2.3a and 6.10.8.2.3b.

D6.4.2—By the Provisions of Article A6.3.3

For unbraced lengths in which the member is prismatic, the flexural resistance based on LTB shall be taken as:

- If $L_b \leq L_p$, then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{D6.4.2-1})$$

- If $L_p < L_b \leq L_r$, then:

$$\text{○ If } L_b \leq L_p + \left(1 - \frac{1}{C_b}\right) \left(\frac{F_{yr} S_{xc}}{R_{pc} M_{yc}}\right) (L_r - L_p), \text{ then:}$$

$$M_{nc} = R_{pc} M_{yc} \quad (\text{D6.4.2-2})$$

- Otherwise:

$$M_{nc} = C_b \left[1 - \left(1 - \frac{F_{yr} S_{xc}}{R_{pc} M_{yc}} \right) \left(\frac{L_b - L_p}{L_r - L_p} \right) \right] R_{pc} M_{yc} \leq R_{pc} M_{yc} \quad (\text{D6.4.2-3})$$

- If $L_b > L_r$, then:

- If:

$$L_b \leq 1.95 r_t \frac{C_b S_{xc} E}{R_{pc} M_{yc}} \sqrt{\frac{J}{S_{xc} h}} \sqrt{1 + \sqrt{1 + 6.76 \left(\frac{R_{pc} M_{yc} S_{xc} h}{C_b S_{xc} E J} \right)^2}}$$

then:

$$M_{nc} = R_{pc} M_{yc} \quad (\text{D6.4.2-4})$$

- Otherwise:

$$M_{nc} = F_e S_{xc} \leq R_{pc} M_{yc} \quad (\text{D6.4.2-5})$$

All terms in the above equations shall be taken as defined in Article A6.3.3.1.

CD6.4.2

For values of the moment-gradient modifier, C_b , greater than 1.0, the maximum LTB resistance M_{max} shown in Figure C6.10.8.2.1-1 may be reached at larger unbraced lengths. The provisions in this Article are equivalent to those in Article A6.3.3, but allow the Engineer to focus on the conditions for which the LTB resistance is equal to $M_{max} = R_{pc} M_{yc}$ when the effects of moment gradient are included in determining the limits on L_b .

The largest unbraced length for which the LTB resistance of Article A6.3.3 is equal to the FLB or FLB resistance of Article A6.3.2 may be determined by substituting $M_{nc(FLB)}$ for $R_{pc} M_{yc}$ in checking the L_b requirement for the use of Eq. D6.4.2-2 or D6.4.2-4 as applicable, where $M_{nc(FLB)}$ is the FLB resistance obtained from Article A6.3.2.

Article A6.3.3 typically requires similar to somewhat smaller values than Article 6.10.8.2.3 for the limits on L_b required to reach the member resistance of $M_{max} > R_{hh} M_{yc}$, depending on the magnitude of R_{pc} . If $D_e t_w / b_{fc} t_{fc}$ in Eq. 6.10.8.2.3b-3 is taken as a representative value of 2.0, F_{yr} is taken as 50 ksi, and $F_{yw} > 0.7 F_{yc}$, then for $R_{pc} = 1.12$, the LTB resistance of this Article is typically equal to M_{max} when $L_b < 22 b_{fc}$ for $C_b > 1.75$ and when $L_b < 15 b_{fc}$ for $C_b > 1.30$. For $R_{pc} = 1.30$ and using the above assumptions, M_{max} is achieved by the LTB equations when $L_b < 20 b_{fc}$ for $C_b > 1.75$ and when $L_b < 13 b_{fc}$ for $C_b > 1.30$. The Engineer should note that, even with relatively small values of C_b , the unbraced length requirements to achieve a flexural resistance of M_{max} are significantly larger than those associated with uniform major-axis bending and $C_b = 1$. Article C6.10.8.2.3b discusses the appropriate calculation of $C_b > 1$ for bridge design.

D6.5—CONCENTRATED LOADS APPLIED TO WEBS WITHOUT BEARING STIFFENERS

D6.5.1—General

At bearing locations and at other locations subjected to concentrated loads, where the loads are not transmitted through a deck or deck system, webs without bearing stiffeners shall be investigated for the limit states of web local yielding and web crippling according to the provisions of Articles D6.5.2 and D6.5.3.

D6.5.2—Web Local Yielding

Webs subject to compressive or tensile concentrated loads shall satisfy:

$$R_u \leq \phi_b R_n \quad (\text{D6.5.2-1})$$

in which:

R_n = nominal resistance to the concentrated loading (kip)

- For interior-pier reactions and for concentrated loads applied at a distance from the end of the member that is greater than d :

$$R_n = (5k + N) F_{yw} t_w \quad (\text{D6.5.2-2})$$

- Otherwise:

$$R_n = (2.5k + N) F_{yw} t_w \quad (\text{D6.5.2-3})$$

where:

ϕ_b = resistance factor for bearing, specified in Article 6.5.4.2

CD6.5.1

The equations of this Article are essentially identical to the equations given in AISC (2022b). The limit state of sidesway web buckling given in AISC (2022b) is not included because it governs only for members subjected to concentrated loads directly applied to the steel section, and for members for which the compression flange is braced at the load point, the tension flange is unbraced at this point, and the ratio of D/t_w to L_b/b_{fl} is less than or equal to 1.7. These conditions typically do not occur in bridge construction.

Built-up sections and rolled shapes without bearing stiffeners at the indicated locations should either be modified to comply with these requirements, or else bearing stiffeners designed according to the provisions of Article 6.10.11.2 should be placed on the web at the location under consideration.

For unusual situations in which diametrically opposed concentrated loads are directly applied to the web of the steel section at the level of each of the flanges, such as if a concentrated force were applied directly over a reaction point at an unstiffened location along the length of a girder, the AISC (2022b) provisions pertaining to additional stiffener requirements for concentrated forces should be considered.

CD6.5.2

This limit state is intended to prevent localized yielding of the web resulting from either high compressive or tensile stress due to a concentrated load or bearing reaction.

A concentrated load acting on a rolled shape or a built-up section is assumed critical at the toe of the fillet located a distance k from the outer face of the flange resisting the concentrated load or bearing reaction, as applicable. For a rolled shape, k is published in the available tables giving dimensions for the shapes. For a built-up section, k may be taken as the distance from the outer face of the flange to the web toe of the web-to-flange fillet weld.

In Eq. D6.5.2-2 for interior loads or interior-pier reactions, the load is assumed to distribute along the web at a slope of 2.5 to 1 and over a distance of $(5k + N)$. An interior concentrated load is defined as a load applied at a distance from the end of the member that is greater than the depth of the steel section, d . In Eq. D6.5.2-3 for end loads or end reactions, the load is assumed to distribute along the web at the same slope over a distance of $(2.5k + N)$. These criteria are largely based on the work of Johnston and Kubo (1941) and Graham et al. (1959).

- d = depth of the steel section (in.)
 k = distance from the outer face of the flange resisting the concentrated load or bearing reaction to the web toe of the fillet (in.)
 N = length of bearing (in.). N shall be greater than or equal to k at end bearing locations.
 R_u = factored concentrated load or bearing reaction (kip)

D6.5.3—Web Crippling

Webs subject to compressive concentrated loads shall satisfy:

$$R_u \leq \phi_w R_n \quad (\text{D6.5.3-1})$$

in which:

R_n = nominal resistance to the concentrated loading (kip)

- For interior-pier reactions and for concentrated loads applied at a distance from the end of the member that is greater than or equal to $d/2$:

$$R_n = 0.8t_w^2 \left[1 + 3 \left(\frac{N}{d} \right) \left(\frac{t_w}{t_f} \right)^{1.5} \right] \sqrt{\frac{EF_{yw}t_f}{t_w}} \quad (\text{D6.5.3-2})$$

- Otherwise:

- If $N/d \leq 0.2$, then:

$$R_n = 0.4t_w^2 \left[1 + 3 \left(\frac{N}{d} \right) \left(\frac{t_w}{t_f} \right)^{1.5} \right] \sqrt{\frac{EF_{yw}t_f}{t_w}} \quad (\text{D6.5.3-3})$$

- If $N/d > 0.2$, then:

$$R_n = 0.4t_w^2 \left[1 + \left(\frac{4N}{d} - 0.2 \right) \left(\frac{t_w}{t_f} \right)^{1.5} \right] \sqrt{\frac{EF_{yw}t_f}{t_w}} \quad (\text{D6.5.3-4})$$

where:

- ϕ_w = resistance factor for web crippling, specified in Article 6.5.4.2
 t_f = thickness of the flange resisting the concentrated load or bearing reaction (in.)

CD6.5.3

This limit state is intended to prevent local instability or crippling of the web resulting from a high compressive stress due to a concentrated load or bearing reaction.

Eqs. D6.5.3-2 and D6.5.3-3 are based on research by Roberts (1981). Eq. D6.5.3-4 for $N/d > 0.2$ was developed after additional testing by Elgaaly and Salkar (1991) to better represent the effect of longer bearing lengths at the ends of members.

D6.6—ELASTIC LTB LOAD RATIO, γ_e , FOR NONPRISMATIC UNBRACED LENGTHS OF I-SECTION MEMBERS

D6.6.1—General

For nonprismatic unbraced lengths of I-section members, the elastic LTB load ratio, γ_e , may be estimated using one of the methods specified in Articles D6.6.2, D6.6.3, or D6.6.4, i.e., Method A, Method B, or Method C.

Method A may also be alternatively used to estimate γ_e for prismatic composite unbraced lengths subjected to reverse curvature bending and prismatic noncomposite unbraced lengths of singly symmetric I-section members subjected to reverse curvature bending.

D6.6.2—Calculation of the Elastic LTB Load Ratio, γ_e —Method A

The elastic LTB load ratio, γ_e , for general nonprismatic unbraced lengths of I-section members, and alternatively for:

- Prismatic composite unbraced lengths of I-section members subjected to reverse curvature bending; and
- Prismatic noncomposite unbraced lengths of singly symmetric I-section members subjected to reverse curvature bending;

may be estimated using Method A as follows:

$$\gamma_e = \frac{\chi C_{be}}{\left(\frac{M_u}{M_{e1}} \right)_{\max}} \quad (\text{D6.6.2-1})$$

in which:

C_{be} = moment-gradient modifier for elastic LTB

$$C_{be} = \frac{12.5 \left(\frac{M_u}{M_{e1}} \right)_{\max}}{2.5 \left(\frac{M_u}{M_{e1}} \right)_{\max} + 3 \left(\frac{M_A}{M_{e1A}} \right) + 4 \left(\frac{M_B}{M_{e1B}} \right) + 3 \left(\frac{M_C}{M_{e1C}} \right)} \quad (\text{D6.6.2-2})$$

where:

M_A, M_B, M_C = absolute value of the factored major-axis bending moment at one-quarter, one-half and three-quarters of the unbraced length under consideration (points A, B, and C), respectively, calculated from the moment

CD6.6.2

Method A is based on the approach documented in AISC Design Guide 25 (White et al., 2021a) to estimate the elastic LTB load ratio, γ_e , for general nonprismatic unbraced lengths of I-section members, including members with a variable web depth and with or without cross-section transitions within the unbraced length under consideration, subject to single- or reverse curvature bending (Slein et al.; 2022a, 2022b, 2022c).

Eq. D6.6.2-1, and the calculation of C_{be} using Eq. D6.6.2-2, may be equivalently written in terms of either moment or stress, since $M_{e1} = F_{e1} S_{xc}$ and $M_u = f_{bu} S_{xc}$. Eq. D6.6.2-1 is derived from the following relationship:

$$\gamma_e M_u = \chi C_{be} M_{e1} \quad (\text{CD6.6.2-1})$$

written at the location where M_u/M_{e1} is maximum. The term $\gamma_e M_u$ is the moment at this cross-section at incipient elastic buckling of the unbraced length under consideration, M_{e1} is the elastic buckling moment associated with the direction of M_u at this location, calculated taking $C_b = 1.0$. C_{be} is a moment-gradient modifier for elastic LTB, which accounts for the variation in M_u relative to M_{e1} among the points considered in the equation for C_b , and χ is a nonprismatic geometry modification factor that accounts for the attributes of the nonprismatic geometry.

Eq. 6.10.8.2.3b-1 is adopted from AISC (2022b). Eq. D6.6.2-2 extends Eq. 6.10.8.2.3b-1 in a straightforward manner for handling of nonprismatic member geometry and/or reverse curvature bending. For prismatic section members subjected to reverse curvature bending, only two values of M_{e1} are needed in Eq. D6.6.2-2, one for each sign of the bending moment. The C_{be} value from Eq. D6.6.2-2 may be taken equal to 1.0 as a conservative simplification.

Slein et al. (2022a and 2022c) provide example design calculations using Method A and discuss comparisons of various methods for determining the

envelope values that produce the largest flexural compression in the flange under consideration at these points, or the smallest flexural tension in this flange if the flange is never in compression at the point. For locations A, B, or C in unbraced lengths of noncomposite or composite section members where the flange under consideration is subjected to compression and is continuously braced within either quarter portion of the unbraced length adjacent to the point under consideration, the moment corresponding to that point, A, B, or C, shall be taken equal to zero in Eq. D6.6.2-2 (kip-in.)

elastic LTB load ratio, γ_e , for different nonprismatic member geometries.

$M_{e1A}, M_{e1B},$
 M_{e1C} = elastic LTB moment at the section under consideration, $F_{e1}S_{xc}$, based on the direction of bending at the section calculated at one-quarter, one-half and three-quarters of the unbraced length under consideration (points A, B, and C), respectively (kip-in.)

F_{e1} = elastic LTB stress corresponding to the flange subjected to flexural compression at the section under consideration, and with C_b taken equal to 1.0, calculated from Eq. 6.10.8.2.3b-2 or Eq. A6.3.3.2-1 as applicable; if the web of the member is slender at any cross-section of the unbraced length, Eq. 6.10.8.2.3b-2 shall apply (ksi). In the calculation of F_{e1} , the radius of gyration for LTB, r_y , may be taken as specified in Eq. 6.10.8.2.3b-3.

M_u = factored major-axis bending moment at the section under consideration (kip-in.)

$\left(\frac{M_u}{M_{e1}} \right)_{\max}$ = maximum ratio of the factored major-axis

bending moment within the unbraced length under consideration, including the end cross-sections, to the elastic LTB moment for the unbraced length, $M_{e1} = F_{e1}S_{xc}$, with F_e determined from Eq. 6.10.8.2.3b-2 or Eq. A6.3.3.2-1 as applicable, and with C_b taken equal to 1.0; M_u is calculated from the moment envelope values that produce the largest flexural compression in the flange under consideration, and M_{e1} is calculated for the direction of bending causing flexural compression in the flange under consideration; if the web of the member is slender at any cross-section of the unbraced length, including the end cross-sections, Eq. 6.10.8.2.3b-2 shall apply (kip-in.).

S_{xc} = elastic section modulus about the major axis of the section to the compression flange (in.³)

χ = nonprismatic geometry modification factor, taken as 1.0 for prismatic unbraced lengths of I-section members, and calculated using the provisions of Articles D6.6.2.1 and D6.6.2.2,

as applicable, for nonprismatic unbraced lengths of I-section members.

D6.6.2.1—Nonprismatic Geometry Modification Factor, χ , for I-Section Members with Prismatic Flanges and a Linear or a Concave Curved Variation of the Web Depth within the Unbraced Length under Consideration

CD6.6.2.1

For I-section members with prismatic flanges and a linear or a concave curved variation of the web depth within the unbraced length under consideration, the elastic LTB load ratio, γ_e , may be estimated using Eqs. D6.6.2.1 and D6.6.2.2, with the nonprismatic geometry modification factor, χ , determined as follows:

The nonprismatic geometry modification factor, χ , accounts for stability effects induced by geometry and cross-section properties independent of the moment gradient. The development of Eqs. D6.6.2.1-1 and D6.6.2.1-2 is discussed further in Slein and White (2019) and Slein et al. (2022a and 2022c).

- For cases where the flange corresponding to I_{yP} is discretely braced and $I_{yV} / I_{yP} > 1.0$:

$$\chi = 1 - 0.02\beta \left(1 - \frac{1}{I_{yV} / I_{yP}} \right) \quad (\text{D6.6.2.1-1})$$

- For all other cases:

$$\chi = 1.0 \quad (\text{D6.6.2.1-2})$$

where:

β = angle between the flanges of the I-section for a linear variation in the web depth, or angle of the chord between the bottom of the web at each end of the unbraced length for a concave parabolic variation in web-depth, taken as positive in all cases (degrees)

I_{yV} = lateral moment of inertia of the flange that follows the variation in the web depth, taken about an axis normal to the flange and in the plane of the web (in.⁴)

I_{yP} = lateral moment of inertia of the flange opposite to the one that follows the variation in the web depth, taken about a vertical axis in the plane of the web (in.⁴)

In order to utilize the χ factor determined as specified herein, the maximum chord angle, β , shown in Figure D6.6.2.1-1 should be less than or equal to 10 degrees. Additionally, the overhang length shown in Figure D6.6.2.1-1 should be less than or equal to $0.2L_b$, where L_b is the unbraced length.

Figure D6.6.2.1-1—Example Member with a Concave Parabolic Haunch and an Overhang

For members with one or more cross-section transitions and a linear or a concave curved variation of the web depth within the unbraced length under consideration, the provisions of Article D6.6.2.2 shall also apply.

For members with a convex curved variation of the web depth within the unbraced length under consideration, the provisions herein may be used by approximating the variation of the web depth as a linear variation of the depth.

D6.6.2.2—Calculation of γ_e for I-Section Members with Cross-Sections Transitions within the Unbraced Length under Consideration

For I-section members containing cross-section transitions within the unbraced length under consideration, the elastic LTB load ratio, γ_e , may be estimated using Eqs. D6.6.2-1 and D6.6.2-2 with the following modifications:

- If there are one or more steps within the quarter-lengths adjacent to Point A, then:

Take M_{e1A} in $\frac{M_A}{M_{e1A}}$ as the minimum elastic LTB moment for the cross-sections within 0 to $0.5L_b$.

- If there are one or more steps within the quarter-lengths adjacent to Point B, then:

Take M_{e1B} in $\frac{M_B}{M_{e1B}}$ as the minimum elastic LTB moment within $0.25L_b$ to $0.75L_b$.

- If there are one or more steps within the quarter-lengths adjacent to Point C, then:

Take M_{e1C} in $\frac{M_C}{M_{e1C}}$ as the minimum elastic LTB moment within $0.5L_b$ to L_b .

CD6.6.2.2

When there are one or more cross-section steps within the quarter-lengths adjacent to Points A, B, or C, M_{e1} in the respective ratio is conservatively taken as the minimum M_{e1} within the adjacent quarter-lengths. This modification accounts for the lack of resolution of Eq. D6.6.2-2, i.e., the quarter-point C_{be} equation samples the M_u/M_{e1} values only at a maximum of four points, and only at three points when the maximum value is at A, B, or C. Eq. D6.6.2.2-1 captures the impact of shifts in the shear center at cross-section step locations in an accurate to conservative manner (Slein and White, 2019) (Slein et al., 2022a). Additionally, if the member also has a variable web depth, the combined modification to C_{be} using the χ factor equations from Article D6.6.2.1 gives an accurate to conservative estimate of the LTB capacity.

To assist in the determination of the value of d_{Smax} in Eq. D6.6.2.2-1, the vertical distance to the shear center of the steel cross-section measured from the center of the compression flange may be computed as:

$$e = \frac{h_o b_{ft}^3 t_{ft}}{b_{fc}^3 t_{fc} + b_{ft}^3 t_{ft}} \quad (\text{CD6.6.2.2-1})$$

where:

- b_{fc} = width of the compression flange (in.)
- b_{ft} = width of the tension flange (in.)
- h_o = distance between flange centroids (in.)

For the calculation of γ_e as specified herein, the steps in the cross-section shall be limited to a change in the lateral moment of inertia of the flanges, calculated as specified in Article 6.10.8.2.3c or Article A6.3.3.3, as applicable, of no more than a factor of 2.0 at any step. Adjacent steps closer than 25 percent of the unbraced length shall be limited to a total change in the lateral moment of inertia of the flanges of no more than a factor of 2.0.

For I-section members containing cross-section transitions within the unbraced length under consideration:

$$\chi = 1 - 4 \frac{d_{Smax}}{L_b} \quad (D6.6.2.2-1)$$

where:

- d_{Smax} = maximum shift in the shear center of the steel cross-section due to the step in the cross-section geometry at any position along the unbraced length, or at any combination of steps that are less than $0.25L_b$ from one another (in.)
- L_b = unbraced length (in.)

If the member has a variable web depth in addition to cross-section transitions, the total χ factor used in Eq. D6.6.2-1 shall be the χ factor specified in Article D6.6.2.1, with I_{yV}/I_{yP} taken as the corresponding maximum ratio within the unbraced length, multiplied by the χ factor from Eq. D6.6.2.2-1.

D6.6.3—Calculation of the Elastic LTB Load Ratio, γ_e —Method B

The elastic lateral-torsional buckling load ratio, γ_e , for:

- constant-web-depth I-section members with cross-section transitions within the unbraced length and
- I-section members with a variable web depth and with or without cross-section transitions within the unbraced length

may be estimated using Method B.

For the computation of γ_e using Method B, the nonprismatic unbraced length shall be replaced with a prismatic unbraced length with effective section properties. The effective section properties shall be computed using a nonlinear length weighted average approach as follows:

- For constant-web-depth members within the unbraced length under consideration, the effective

- t_{fc} = thickness of the compression flange (in.)
- t_{ft} = thickness of the tension flange (in.)

CD6.6.3

Method B is based on the use of a weighted-average section approach and traditional moment-gradient expressions to estimate the elastic LTB load ratio, γ_e , for constant-web-depth I-section members with cross-section transitions within the unbraced length and for I-section members with a variable web depth and with or without cross-section transitions within the unbraced length (Reichenbach et al.; 2020, 2024).

In this method, the nonprismatic unbraced length is replaced with a prismatic unbraced length with effective section properties for the estimation of γ_e from Eq. D6.6.3-12. Effective top and/or bottom flange widths and thicknesses and/or web thicknesses for nonprismatic flanges and/or webs within the unbraced length are computed from Eqs. D6.6.3-4 through D6.6.3-6, as applicable. These equations essentially treat all sections larger than the smallest section equivalent to the second-smallest section within the unbraced length, which was found to provide reasonably accurate predictions for the LTB resistance of a nonprismatic member with up to three distinct cross-sections within the unbraced length.

web depth, D_{eff} , shall be taken as D . Otherwise, for a variable web depth within the unbraced length:

$$D_{taper} = D_{small}[1 - (1 - 0.5)^4] + D_2(1 - 0.5)^4 \quad (D6.6.3-1)$$

- If the variable web depth does not extend over the entire unbraced length, D_{taper} , from Eq. D6.6.3-1 shall be substituted for D_{small} or D_2 , as appropriate, in the following equation to compute the effective web depth, D_{eff} :

$$D_{eff} = D_{small}[1 - (1 - x_{small})^4] + D_2(1 - x_{small})^4 \quad (D6.6.3-2)$$

- Otherwise:

$$D_{eff} = D_{taper} \quad (D6.6.3-3)$$

- For prismatic top and/or bottom flanges and/or webs within the unbraced length under consideration, the effective flange width, $b_{f,eff}$, effective flange thickness, $t_{f,eff}$, and/or effective web thickness, $t_{w,eff}$, shall be taken as b_f , t_f , and/or t_w , respectively. Otherwise, $b_{f,eff}$, $t_{f,eff}$, and/or $t_{w,eff}$ may be computed as follows:

$$b_{f,eff} = b_{f,small} \left[1 - (1 - x_{small})^2 \right] + b_{f,2} (1 - x_{small})^2 \quad (D6.6.3-4)$$

$$t_{f,eff} = t_{f,small} \left[1 - (1 - x_{small})^2 \right] + t_{f,2} (1 - x_{small})^2 \quad (D6.6.3-5)$$

$$t_{w,eff} = t_{w,small} \left[1 - (1 - x_{small})^2 \right] + t_{w,2} (1 - x_{small})^2 \quad (D6.6.3-6)$$

where:

- b_f = flange width (in.)
- $b_{f,small}$ = flange width at the smallest cross-section within the unbraced length under consideration (in.)
- $b_{f,2}$ = flange width at the second smallest cross-section within the unbraced length under consideration (in.)
- D = web depth (in.)
- D_{small} = smallest web depth within the unbraced length under consideration (in.)
- D_2 = largest web depth within the unbraced length under consideration (in.)
- t_f = flange thickness (in.)
- $t_{f,small}$ = flange thickness at the smallest cross-section within the unbraced length under consideration (in.)
- $t_{f,2}$ = flange thickness at the second smallest cross-section within the unbraced length under consideration (in.)

For I-section members with a concave or convex curved variation of the web depth within the unbraced length under consideration, the variation of the web depth is approximated as a linear variation of the depth. Therefore, for a variable web depth within the unbraced length, the effective web depth, D_{taper} , is computed first from Eq. D6.6.3-1. If the variable web depth does not extend over the entire unbraced length, D_{taper} is substituted for D_{small} or D_2 , as appropriate, in Eq. D6.6.3-2 for the effective web depth, D_{eff} , with x_{small} taken as the fraction of the total unbraced length under consideration comprising the cross-section having the smallest depth in the newly transformed stepped web depth member. If the variable web depth does extend over the entire unbraced length, then D_{eff} is simply taken equal to D_{taper} . If one or more cross-section components are also nonprismatic along the unbraced length, the effective widths and/or thicknesses of those components computed separately from Eqs. D6.6.3-4 through D6.6.3-6, as applicable, are used along with D_{eff} in the computation of the effective section properties. If one or more cross-section components are prismatic within the unbraced length, the nominal dimensions are used for those components along with D_{eff} in the computation of the effective section properties.

For the calculation of C_{be} from Eq. D6.6.3-10 for singly symmetric noncomposite members subject to reverse curvature bending, the value of ρ_{Top} in Eq. C6.10.8.2.3b-3 for R_m should be taken as the value of ρ_{Top} for the smallest section within the unbraced length under consideration (Reichenbach et al., 2020).

- t_w = web thickness (in.)
 $t_{w,small}$ = web thickness at the smallest cross-section within the unbraced length under consideration (in.)
 t_{w2} = web thickness at the second smallest cross-section within the unbraced length under consideration (in.)
 x_{small} = fraction of the total unbraced length under consideration comprising the smallest cross-section.

The radius of gyration for LTB for the prismatic unbraced length with the effective cross-section, $r_{t,eff}$, used to calculate the elastic LTB stress for that length, $F_{e,eff}$, from Eq. D6.6.3-8 or D6.6.3-9, as applicable, shall be taken as:

$$r_{t,eff} = \frac{b_{fc,eff}}{\sqrt{12 \left(1 + \frac{1}{3} \frac{D_{c,eff} t_{w,eff}}{b_{fc,eff} t_{fc,eff}} \right)}} \quad (D6.6.3-7)$$

where:

- $b_{fc,eff}$ = effective flange width corresponding to the flange subject to flexural compression within the unbraced length under consideration (in.)
 $D_{c,eff}$ = depth of the web in compression in the elastic range for the effective cross-section within the unbraced length under consideration (in.). For composite sections, D_c shall be determined as specified in Article D6.3.1.
 $t_{fc,eff}$ = effective flange thickness corresponding to the flange subject to flexural compression within the unbraced length under consideration (in.)
 $t_{w,eff}$ = effective web thickness within the unbraced length under consideration (in.)

The elastic LTB stress for the prismatic unbraced length with the effective cross-section, $F_{e,eff}$, used to calculate γ_e from Eq. D6.6.3-12 shall be taken as one of the following, as applicable:

- For unbraced lengths in which the LTB parameters are computed from Article 6.10.8.2.3c:

$$F_{e,eff} = \frac{C_{bc} \pi^2 E}{\left(\frac{L_b}{r_{t,eff}} \right)^2} \quad (D6.6.3-8)$$

- For unbraced lengths in which the LTB parameters are computed from Article A6.3.3.3:

$$F_{e,eff} = \frac{C_{bc} \pi^2 E}{\left(L_b / r_{t,eff} \right)^2} \sqrt{1 + 0.078 \frac{J_{eff}}{S_{xc,eff} h_{eff}} \left(L_b / r_{t,eff} \right)^2} \quad (D6.6.3-9)$$

in which:

C_{be} = moment-gradient modifier for elastic LTB

$$C_{be} = \frac{12.5M_{\max}}{2.5M_{\max} + 3M_A + 4M_B + 3M_C} \quad (\text{D6.6.3-10})$$

J_{eff} = St. Venant torsional constant for the prismatic unbraced length with the effective cross-section (in.⁴)

$$J_{eff} = \frac{D_{eff}^3 t_{w,eff}^3}{3} + \frac{b_{fc,eff} t_{fc,eff}^3}{3} \left(1 - 0.63 \frac{t_{fc,eff}}{b_{fc,eff}} \right) + \frac{b_{ft,eff} t_{ft,eff}^3}{3} \left(1 - 0.63 \frac{t_{ft,eff}}{b_{ft,eff}} \right) \quad (\text{D6.6.3-11})$$

where:

$b_{fc,eff}$ = effective flange width corresponding to the flange subject to flexural compression within the unbraced length under consideration (in.)

$b_{ft,eff}$ = effective flange width corresponding to the flange subject to flexural tension within the unbraced length under consideration (in.)

D_{eff} = effective web depth within the unbraced length under consideration (in.)

h_{eff} = depth between the centerline of the flanges of the effective cross-section (in.)

L_b = unbraced length (in.). For cases in single-curvature bending, where continuous bracing of a flange subjected to compression ends, the unbraced length shall be taken as the distance from the end of the continuous bracing to the adjacent location of a discrete brace; otherwise, the unbraced length shall be taken as the full unbraced length between the discrete brace locations.

M_A, M_B, M_C = absolute value of the factored major-axis bending moment at one-quarter, one-half and three-quarters of the unbraced length under consideration (points A, B, and C), respectively, calculated from the moment envelope values that produce the largest flexural compression in the flange under consideration at these points, or the smallest flexural tension in this flange if the flange is never in compression at the point. For locations A, B, or C in unbraced lengths of noncomposite or composite section members where the flange under

consideration is subjected to compression and is continuously braced within either quarter portion of the unbraced length adjacent to the point under consideration, the moment corresponding to that point, A, B, or C, shall be taken equal to zero in Eq. D6.6.3-10 (kip-in.)

M_{max} = absolute value of the factored maximum major-axis moment in the unbraced length, calculated from the moment envelope value that produces the largest flexural compression in the flange under consideration (kip-in.)

$S_{xc\ eff}$ = elastic section modulus about the major axis of the section to the compression flange of the effective cross-section (in.³)

$t_{fc\ eff}$ = effective flange thickness corresponding to the flange subject to flexural compression within the unbraced length under consideration (in.)

$t_{ft\ eff}$ = effective flange thickness corresponding to the flange subject to flexural tension within the unbraced length under consideration (in.)

$t_{w\ eff}$ = effective web thickness within the unbraced length under consideration (in.)

The elastic lateral-torsional buckling load ratio, γ_e , may be estimated as:

$$\gamma_e = \frac{F_{e\ eff} S_{xc\ eff}}{M_{u\ max}} \quad (D6.6.3-12)$$

where:

$M_{u\ max}$ = maximum factored major-axis bending moment within the unbraced length under consideration, including the end cross-sections, calculated from the moment envelope values that produces the largest flexural compression in the flange under consideration (kip-in.)

For the calculation of γ_e as specified herein, the steps in the cross-section shall be limited to a change in the lateral moment of inertia of the flanges, calculated as specified in Article 6.10.8.2.3c or Article A6.3.3.3, as applicable, of no more than a factor of 2.0 at any step. Adjacent steps closer than 25 percent of the unbraced length shall be limited to a total change in the lateral moment of inertia of the flanges of no more than a factor of 2.0.

D6.6.4—Calculation of the Elastic LTB Load Ratio, γ_e —Method C

For unbraced lengths in which an I-section member is nonprismatic within the unbraced length and does not

CD6.6.4

In Method C, the elastic LTB load ratio, γ_e , is estimated as the eigenvalue from an elastic buckling

meet the specified conditions for the application of Method A in Article D6.6.2 or Method B in Article D6.6.3, or for cases where a more refined estimate of the member resistance is desired, the elastic LTB load ratio, γ_e , may be estimated as the eigenvalue from an elastic buckling analysis using a thin-walled open-section member model or an elastic three-dimensional shell-element model that captures the significant effects of the nonprismatic geometry.

analysis using a thin-walled open-section member model or an elastic three-dimensional shell-element model.

For unbraced lengths of general nonprismatic members, γ_e is estimated most reliably using elastic buckling analysis software tools; for example, White et al. (2021b). These software calculations should be based on thin-walled open-section beam theory and must capture the significant effects of the nonprismatic geometry; that is, web taper, steps in the cross-section, and lateral and torsional restraint as appropriate based on the physical characteristics of the member. The web distortional flexibility must be accounted for in cases where torsional restraint from the bridge deck is considered. This may be accomplished using Eq. CA6.6.3.2-2. One typical practice is to model the unbraced length with idealized flexurally and torsionally simply supported end conditions, i.e., warping and flange lateral bending assumed to be unrestrained at the ends of the unbraced length, with applied end moments from a global analysis model and any transverse loads within the unbraced length included.

In addition, White et al. (2016, 2020, 2021a) discuss the use of software tools that capture the inelastic stiffness reduction implicit in the Specification LTB resistance equations, allowing an alternative rigorous and direct calculation of the design LTB resistance via an inelastic buckling analysis based on thin-walled open-section beam theory.

APPENDIX E6—NOMINAL COMPRESSIVE RESISTANCE OF NONCOMPOSITE MEMBERS CONTAINING LONGITUDINALLY STIFFENED PLATES

E6.1—NOMINAL COMPRESSIVE RESISTANCE

E6.1.1—General

For noncomposite compression member cross-sections containing any longitudinally stiffened plates, the nominal compressive resistance, P_n , shall be taken as the smallest value based on the applicable modes of flexural buckling, torsional buckling, and flexural-torsional buckling, and shall be computed as follows:

$$P_n = \chi F_{cr} A_{eff} \quad (\text{E6.1.1-1})$$

in which:

- For noncomposite rectangular box cross-sections containing one or more longitudinally stiffened flange plates in the direction associated with column flexural buckling, and where $\lambda_{max} > \lambda_{rs}$,

$$\chi = 1 - r_1 r_2 \quad (\text{E6.1.1-2})$$

$$r_1 = 0.5 (K \ell / r_x - 50) / 90 \geq 0 \quad (\text{E6.1.1-3})$$

$$r_2 = \frac{\lambda_{max} - \lambda_r}{90 - \lambda_r} \geq 0 \quad (\text{E6.1.1-4})$$

- Otherwise:

$$\chi = 1.0 \quad (\text{E6.1.1-5})$$

- If $\frac{P_{os}}{P_e} \leq 2.25$:

$$F_{cr} = \left[0.658 \left(\frac{P_{os}}{P_e} \right) \right] F_y \quad (\text{E6.1.1-6})$$

- Otherwise:

$$F_{cr} = 0.877 \frac{P_e}{P_{os} / F_y} \quad (\text{E6.1.1-7})$$

A_{eff} = effective area of the cross-section (in.²)

$$= \sum_{lusp} b_e t + \sum_c A_c + \sum_{bsp} (A_{eff})_{sp} \quad (\text{E6.1.1-8})$$

P_{os} = nominal yield resistance (kip)

$$= F_y \left(\sum_{lusp} b t + \sum_c A_c + \sum_{bsp} (A_{eff})_{sp} \right) \quad (\text{E6.1.1-9})$$

CE6.1.1

This Article implements an extension of the unified effective width/unified effective area method, described further in Article C6.9.4.2.2a, incorporating the consideration of longitudinally stiffened component plates. Eqs. E6.1.1-1 through E6.1.1-9 capture the influence of buckling of individual longitudinally unstiffened and longitudinally stiffened plates on the overall member axial compressive resistance in a simple yet accurate to conservative manner (White et al., 2019b).

Longitudinally stiffened plates are addressed by adding their effective cross-sectional area, $(A_{eff})_{sp}$, calculated based on the yield strength of the stiffened plate, with the gross areas of the other components of the cross-section to determine the nominal yield resistance of the cross-section, P_{os} , given by Eq. E6.1.1-9. In addition, $(A_{eff})_{sp}$ is combined with the effective areas of any longitudinally unstiffened plates and the gross area of the corners of the box-section in Eq. E6.1.1-8 to determine the cross-section effective area. White et al. (2019b) explain the rationale for this approach.

Eqs. E6.1.1-2 through E6.1.1-4 define a strength reduction factor, χ , accounting for local-global buckling interaction effects in noncomposite rectangular box-section members having longitudinally stiffened flange plates with slender panels between the stiffeners in the direction of column flexural buckling. The flange plates are defined as the plates parallel to the axis of buckling, i.e., they are subjected to uniform flexural compression from the bending associated with column flexural buckling.

If λ_{max} is less than or equal to λ_r for the panels of the stiffened flange plates under consideration, χ is equal to 1.0.

The χ factor given by Eqs. E6.1.1-2 to E6.1.1-4 is applicable for specified minimum yield strengths up to $F_y = 70$ ksi, and for $\lambda_{max} \leq 90$ and $K \ell / r_s \leq 140$, which are limits specified in Articles 6.12.2.2.2b and 6.9.3.

For nonhomogeneous members, this Article specifies that F_y may conservatively be taken as the smallest specified yield strength of all the cross-section elements for the calculation of F_{cr} . White et al. (2019b) discuss a more rigorous approach for the determination of the axial compressive resistance of nonhomogeneous members with doubly symmetric I- and box-section profiles.

The terms in Eq. E6.1.1-8 and in Eq. E6.1.1-9 for the effective area of the cross-section, A_{eff} , and nominal yield resistance, P_{os} , are taken as zero when the cross-section does not contain the corresponding plate element type; for example, the first term of Eqs. E6.1.1-8 and E6.1.1-9 is

where:

λ_{max}	=	maximum w/t of the panels within the longitudinally stiffened flange plate under consideration
λ_r	=	nonslender limit for longitudinally stiffened plate panels, defined in Article E6.1.2
$\sum_{lusp}$	=	summation over all longitudinally unstiffened cross-section plates
$\sum_c$	=	summation over all the corner areas of a noncomposite box-section member
$\sum_{lsp}$	=	summation over all the longitudinally stiffened cross-section plates
A_c	=	gross cross-sectional area of the corner pieces of a noncomposite box-section member (in. ²)
$(A_{eff})_{sp}$	=	effective area of the longitudinally stiffened plate under consideration determined as specified in Article E6.1.3 (in. ²)
b	=	width of the longitudinally unstiffened plate under consideration determined as specified in Table 6.9.4.2.1-1 (in.)
b_e	=	effective width of the longitudinally unstiffened plate under consideration, determined as specified in Article 6.9.4.2.2b for slender plate elements, and taken equal to b for nonslender plate elements (in.)
F_y	=	specified minimum yield strength (ksi); for nonhomogeneous cross-section members, F_y may be taken as the smallest specified minimum yield strength of all the cross-section elements in lieu of a more refined calculation
$K\ell$	=	effective length in the plane of buckling (in.)
P_e	=	elastic critical buckling resistance determined as specified in Article 6.9.4.1.2 for flexural buckling, and as specified in Article 6.9.4.1.3 for torsional buckling or flexural-torsional buckling, as applicable, using the gross section properties (kip)
r_s	=	radius of gyration about the axis normal to the plane of buckling calculated using the gross section properties (in.)
t	=	thickness of the longitudinally unstiffened plate under consideration (in.)
w	=	width of the flange plate between the centerlines of the individual longitudinal stiffeners or between the centerline of the longitudinal stiffener and the inside of the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration, as applicable, equal to the tributary width in the case of equally spaced longitudinal stiffeners (in.)

taken as zero if the cross-section contains only longitudinally stiffened plates. The second term of Eqs. E6.1.1-8 and E6.1.1-9 is the total gross cross-sectional area contributed by the four corner pieces of a noncomposite box-section member not included in the clear width of the component plates; for all other members, A_c is taken as zero. Flange extensions on box-section members, if present, should be evaluated to determine if they are nonslender or slender plate elements and included accordingly in Eqs. E6.1.1-8 and E6.1.1-9.

For all cross-section plates that are supported along two longitudinal edges and are slender as defined in Article 6.9.4.2.2a, and for slender panels of longitudinally stiffened plates as defined in Article E6.1.2, the provisions of Article 6.9.4.5 also shall be satisfied.

E6.1.2—Classification of Longitudinally Stiffened Plate Panels

Longitudinally stiffened plate panels satisfying the following limit shall be defined as nonslender under uniform axial compression:

$$\frac{w}{t} \leq \lambda_r \quad (\text{E6.1.2-1})$$

where:

- λ_r = nonslender limit for longitudinally stiffened plate panels, equal to $1.09\sqrt{E/F_{ysp}}$ if the plate has one longitudinal stiffener, or $1.49\sqrt{E/F_{ysp}}$ if the plate has two or more longitudinal stiffeners
- w = width of the plate between the centerlines of the individual longitudinal stiffeners or between the centerline of the longitudinal stiffener and the inside of the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration, as applicable, equal to the tributary width in the case of equally spaced longitudinal stiffeners (in.)
- t = thickness of the longitudinally stiffened plate under consideration (in.)
- F_{ysp} = specified minimum yield strength of the longitudinally stiffened plate under consideration (ksi)

Local buckling effects shall be neglected for nonslender longitudinally stiffened plate panels. Otherwise, a panel of a longitudinally stiffened plate shall be defined as slender under uniform axial compression and its local buckling effects shall be considered using the provisions of Articles E6.1.1 and E6.1.3.

E6.1.3—Nominal Compressive Resistance and Effective Area of Plates with Equally Spaced Equal-Size Longitudinal Stiffeners

The nominal compressive resistance of plates with equally spaced equal-size longitudinal stiffeners, P_{nsp} , shall be determined as follows:

$$P_{nsp} = nP_{ns} + 2P_{nR} \quad (\text{E6.1.3-1})$$

in which:

CE6.1.2

This Article defines the nonslender limit, λ_r , for panels of longitudinally stiffened plates. For panels in plates containing only one longitudinal stiffener, the general λ_r limit from Table 6.9.4.2.1-1 for plate elements supported along two longitudinal edges is employed. For panels in plates containing two or more longitudinal stiffeners, the larger value $1.49\sqrt{E/F_{ysp}}$ is adopted recognizing the larger net buckling and post-buckling resistance due to the edge restraint conditions from adjacent panels (Lokhande and White, 2018).

CE6.1.3

Longitudinal stiffening of web and/or flange plates for compressive resistance can be important to the overall design economy of large box girders, arch ribs and tie girders, and steel towers in longer-span steel bridges. Longitudinal stiffening can be beneficial when reduction of structural weight is a premium, and where the design stresses developed by a corresponding longitudinally unstiffened plate satisfying the strength requirements are

P_{ns} = nominal compressive resistance of an individual stiffener strut composed of the stiffener plus the tributary width of the longitudinally stiffened plate under consideration (kip)

$$= P_{nsF} + 0.15 P_{esT} \leq P_{yes} \quad (\text{E6.1.3-2})$$

and

P_{nR} = nominal compressive resistance provided by an individual laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration (kip)

$$= \left(1 - \frac{P_{ns}}{P_{yes}}\right) \left[0.45 \left(F_{ysp} + \frac{P_{ns}}{A_{es}}\right) A_{gR}\right] + \left(\frac{P_{ns}}{P_{yes}}\right) P_{yeR} \leq P_{yeR} \quad (\text{E6.1.3-3})$$

where:

n = number of longitudinal stiffeners

The following terms apply to the calculation of P_{ns} :

P_{nsF} = nominal flexural buckling resistance of an individual stiffener strut (kip) determined as follows:

- If $\frac{P_{ys}}{P_{esF}} \leq 2.25$, then:

$$P_{nsF} = 0.658 \frac{P_{ys}}{P_{esF}} P_{yes} \quad (\text{E6.1.3-4})$$

- Otherwise:

$$P_{nsF} = 0.877 \frac{P_{esF}}{A_{gs}} A_{es} \quad (\text{E6.1.3-5})$$

P_{esF} = elastic flexural buckling resistance of an individual stiffener strut (kip)

$$= \frac{\pi^2 EI_s}{\ell^2} + \frac{\pi^2 EwI_p}{b_{sp}^4} \ell^2 \quad (\text{E6.1.3-6})$$

I_p = lateral moment of inertia of a unit width of the longitudinally stiffened plate under consideration (in.³)

$$= \frac{t_{sp}^3}{12(1 - \nu^2)} \quad (\text{E6.1.3-7})$$

ℓ = buckling length of the individual stiffener struts, taken equal to the smaller of a and ℓ_c (in.), where:

relatively low due to local buckling effects. In addition, longitudinal stiffening can be beneficial for large plate widths where the required thickness needed to satisfy the strength demands is not available using a longitudinally unstiffened plate.

Typically, longitudinal stiffening should not be considered for total plate widths less than about 60.0 in. Longitudinally unstiffened plates are usually more economical in these cases; thickening the plate rather than adding longitudinal stiffeners may also be more economical for plate widths larger than 60.0 in.

Articles E6.1.3 through E6.1.5 provide a streamlined intuitive approach for the design of longitudinally stiffened plates. Article E6.1.3 addresses the compressive resistance of plates designed using equally spaced, equal-size longitudinal stiffeners. White et al. (2019b) provide an extension of these provisions for calculation of the compressive resistance of stiffened plates using unequally-spaced and/or unequal-size longitudinal stiffeners. These types of plates can be addressed conservatively by neglecting the presence of the longitudinal stiffener or stiffeners and calculating the resistance of the hypothetical longitudinally unstiffened plate.

Eq. E6.1.3-1 implements a unified method for the design of longitudinally stiffened plates with or without transverse stiffeners developed by King (2017) and Lokhande and White (2018). The method considers explicitly the influence of plate bending, plate torsion and longitudinal stiffener flexure, and is derivable both from column on elastic foundation and orthotropic plate buckling idealizations. These three contributions to the buckling resistance are combined in a manner that characterizes the longer strength plateau associated with plate buckling. Explicit combination of the three contributions to the stiffened plate compressive resistance facilitates design optimization since the relative importance of each effect is clear.

The characteristic buckling length of the longitudinal stiffener struts, which is the theoretical length between the inflection points within the buckling mode of the struts for an infinitely long plate, is calculated directly, such that the impact of transverse stiffener or diaphragm spacing can be directly ascertained. The method recognizes the post-buckling resistance of the plate panels between the longitudinal stiffeners, and/or between the longitudinal stiffeners and the laterally restrained longitudinal edge of the stiffened plate. The method also recognizes that the edge stress is larger than the ultimate stress of the stiffener strut, and it takes into account the observation that the edge stress is typically less than yield stress under the ultimate strength condition (Lokhande and White, 2018).

This procedure provides a more explicit, general, accurate and transparent evaluation of the influence of longitudinal and transverse stiffening than prior procedures. Furthermore, it avoids anomalies that occur for certain geometries in the Eurocode Part 1-5

- a = longitudinal spacing between locations of transverse stiffeners or diaphragms that provide transverse lateral restraint to the longitudinally stiffened plate under consideration (in.)
- ℓ_c = characteristic buckling length of the stiffener struts of the longitudinally stiffened plate under consideration (in.)

$$= \left(\frac{I_s}{wI_p} \right)^{1/4} b_{sp} \quad (\text{E6.1.3-8})$$

A_{es} = effective area of an individual stiffener strut (in.²)

$$= A_s + w_e t_{sp} \quad (\text{E6.1.3-9})$$

A_{gs} = gross area of an individual stiffener strut (in.²)

$$= A_s + w t_{sp} \quad (\text{E6.1.3-10})$$

P_{esT} = plate torsional stiffness contribution to the elastic buckling resistance of an individual stiffener strut (kip)

$$= \frac{\pi^2}{(1-\nu)b_{sp}^2} \frac{G w t_{sp}^3}{3} \quad (\text{E6.1.3-11})$$

P_{yes} = effective yield load of an individual stiffener strut (kip)

$$= F_{ysp} A_{es} \quad (\text{E6.1.3-12})$$

P_{ys} = yield load of an individual stiffener strut (kip)

$$= F_{ysp} A_{gs} \quad (\text{E6.1.3-13})$$

where:

ν = Poisson's ratio = 0.3

A_s = gross area of an individual longitudinal stiffener, excluding the tributary width of the longitudinally stiffened plate under consideration (in.²)

b_{sp} = total width of the longitudinally stiffened plate, taken as the inside distance between the plates providing lateral restraint to its longitudinal edges (in.)

F_{ysp} = specified minimum yield strength of the longitudinally stiffened plate under consideration (ksi)

G = shear modulus of elasticity for steel = 0.385E (ksi)

I_s = moment of inertia of an individual stiffener strut composed of the stiffener plus the gross tributary width, w , of the longitudinally stiffened plate under consideration, taken about an axis parallel to the face of the longitudinally stiffened plate and passing through the centroid of the combined area of the longitudinal stiffener and its gross tributary plate width (in.⁴)

procedures (CEN, 2006), which employ an interpolation between a strength curve for unstiffened plates and a buckling curve for compression members.

The term P_{nsF} in Eq. E6.1.3-2 addresses the contribution from the flexural buckling resistance of the longitudinal stiffener struts, including the assistance from the transverse bending stiffness of the plate, via the elastic buckling load term P_{esF} . For cases where the spacing of the transverse stiffening elements, a , is greater than the characteristic buckling length, ℓ_c , given by Eq. E6.1.3-8, and therefore $\ell = \ell_c$, the two contributions to P_{esF} in Eq. E6.1.3-6 are equal and the elastic buckling load may be calculated simply as:

$$P_{esF} = \frac{2\pi^2 E}{b_{sp}^2} \sqrt{wI_p I_s} \quad (\text{CE6.1.3-1})$$

Alternatively, when $\ell = \ell_c$, P_{esF} can simply be taken as two times the result from the first term of Eq. E6.1.3-6.

Given the stiffener strut elastic flexural buckling resistance, the strut nominal flexural buckling resistance is quantified by the familiar AISC/AASHTO column strength equations, Eqs. E6.1.3-4 and E6.1.3-5.

Eq. E6.1.3-2 also addresses the contribution from the torsional stiffness of the plate, via the term $0.15P_{esT}$. The maximum value of P_{ns} is limited to the yield load of the stiffener strut including the effective width of the plate panels tributary to the longitudinal stiffener. The term $0.15P_{esT}$ in Eq. E6.1.3-2 captures the plate elastic torsional stiffness contribution to the resistance of the stiffener struts. This torsional stiffness contribution can be significant for narrow plates with a single longitudinal stiffener, and leads to an increase in strength up to about 7 percent and a lengthening of the strength plateau for these types of plates.

The calculations of this Article may be simplified in certain cases:

- Due to the influence of the $0.15P_{esT}$ term, P_{ns} may be taken equal to the full yield strength of the stiffener struts, P_{ys} , when $P_{ys}/P_{esF} \leq 0.2$ in designs with a single longitudinal stiffener, $\ell = \ell_c$, and when the plate panels are nonslender as defined in Article E6.1.2. Otherwise, when $P_{ys}/P_{esF} \leq 0.1$, the effects of the longitudinal stiffener slenderness are small and P_{ns} in Eq. E6.1.3-2 may be taken equal to P_{yes} .
- For plates with two or more longitudinal stiffeners, the contribution of $0.15P_{esT}$ to the resistance in Eq. E6.1.3-2 is relatively small and may be neglected.
- For plates with nonslender plate panels as defined in Article E6.1.2, the plate panels do not experience any reduction in strength due to local

- t_{sp} = thickness of the longitudinally stiffened plate under consideration (in.)
- w = width of the plate between the centerlines of the individual longitudinal stiffeners or between the centerline of the longitudinal stiffener and the inside of the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration, as applicable, equal to the gross tributary width in the case of equally spaced longitudinal stiffeners (in.)
- w_e = effective width of the plate tributary to each stiffener strut, taken as the corresponding value of b_e calculated as specified in Article 6.9.4.2.2b with w substituted for b , with F_{cr} taken as F_{ysp} and with λ_r taken as specified in Article E6.1.2 (in.)

The following additional terms apply to the calculation of P_{nR} :

- A_{gR} = gross tributary area of the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration (in.²)

$$= \frac{w}{2} t_{sp} \quad (\text{E6.1.3-14})$$

- P_{yeR} = effective yield load of an individual laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration (kip)

$$= F_{ysp} A_{eR} \quad (\text{E6.1.3-15})$$

- A_{eR} = effective tributary area of the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration (in.²)

$$= \frac{w_e}{2} t_{sp} \quad (\text{E6.1.3-16})$$

The longitudinal stiffeners shall satisfy the requirements of Article E6.1.4. Transverse stiffeners, when utilized to strengthen or stiffen a longitudinally stiffened plate, shall satisfy the requirements of Article E6.1.5.

The effective area of plates with equally spaced equal-size longitudinal stiffeners shall be calculated as follows:

$$(A_{eff})_{sp} = \frac{P_{nsp}}{F_{ysp}} \quad (\text{E6.1.3-17})$$

buckling effects. Therefore, $w_e = w$, $A_{eR} = A_{gs}$, and $P_{yeR} = P_{ys}$ for these cases.

The term P_{nR} from Eq. E6.1.3-3 gives the contribution from the laterally restrained longitudinal edges of a longitudinally stiffened plate. This equation specifies a simple linear interpolation between the yield load of the edge, P_{yeR} , based on the plate effective width tributary to the edge, in the limit that P_{ns} is equal to P_{yes} , and the compression force given by $0.45(F_{ysp} + P_{ns}/A_{es})$, acting on A_{gR} , in the limit that P_{ns} becomes small.

Figure CE6.1.3-1 illustrates the definition of a number of the variables in this Article.

Figure CE6.1.3-1—Illustration of Variables for a Longitudinally Stiffened Plate

When the spacing between transverse stiffeners and/or diaphragms is smaller than the characteristic buckling length, ℓ_c , the buckling length of the stiffener struts, ℓ , is taken as the corresponding spacing, a . In this situation, the strength of the stiffened plate is increased due to the transverse stiffening. Otherwise, the spacing of the transverse stiffeners does not have any significant impact on the strength of the stiffened plate. The characteristic buckling length, ℓ_c , is the theoretical length between the inflection points within the buckling mode of the stiffener struts for an infinitely long plate.

The effective area of longitudinally stiffened plates, $(A_{eff})_{sp}$, is employed in Article E6.1.1 in the calculation of the axial compressive resistance of members containing these types of plate elements.

E6.1.4—Longitudinal Stiffeners

Longitudinal stiffeners should consist of a flat rectangular plate, a rib, an angle, or a T-section welded to one side of the plate. The specified minimum yield strength of the stiffeners should not be less than the specified minimum yield strength of the plate to which they are attached.

Longitudinal stiffeners shall be structurally continuous over their specified length and should be continuously welded to the plate.

The cross-section elements of longitudinal stiffeners should satisfy:

CE6.1.4

The provisions contained herein apply generally for the design of the longitudinal stiffeners on all longitudinally stiffened plates.

Early yielding of lower-strength stiffeners would result in a significant reduction in their effectiveness; therefore, the specified minimum yield strength of the stiffeners should not be less than the specified minimum yield strength of the plate to which they are attached. Otherwise, the strength of the stiffened plate may be calculated by taking F_{ysp} equal to the specified minimum yield strength of the stiffeners in Articles E6.1.1 and E6.1.3. T-sections may not be available in higher grades of steel. In these cases, a T-section can be fabricated from plates or bars cut from plate.

Longitudinal stiffeners must be structurally continuous along their length to develop the resistance of the corresponding stiffened plates. Longitudinal stiffeners should either be continuous through any intermediate internal diaphragms or transverse stiffeners, or discontinued and positively attached to each side of the diaphragms or transverse stiffeners such that they act as continuous elements. Cutouts may be used in diaphragms or transverse stiffeners to accommodate continuous longitudinal stiffeners. Where cutouts are used, the longitudinal stiffeners should be attached to the internal diaphragms or transverse stiffeners. T-section longitudinal stiffeners may be conveniently attached to the diaphragms or transverse stiffeners by welds or bolts with a pair of clip angles. A welded tab plate may also be used to make the attachment. Similar attachment of the longitudinal stiffeners should also be considered at end diaphragms.

Should it be necessary to discontinue a longitudinal stiffener at a bolted field splice, consideration should be given to extending the stiffener to the free edge of the plate element, where the normal stress is zero. If the plate element on the other side of the splice is longitudinally unstiffened, its resistance should be checked accordingly to determine if the flange is satisfactory without a stiffener or if a slight increase in the flange thickness will suffice without providing a stiffener. Where necessary to extend the longitudinal stiffener beyond a field splice, splicing the stiffener across the field splice is recommended. The continuity of the longitudinal stiffener and the integrity of the stiffened plate must be maintained across the splice.

If the stiffener is terminated outside the splice and the termination is subject to a net tensile stress, determined as specified in Article 6.6.1.2.1, the termination of the stiffener weld to the plate must be checked for fatigue according to the terminus detail. Terminating the longitudinal stiffener by positively attaching it to a transverse stiffener is also another possible alternative, which may lead to a larger fatigue resistance.

Eq. E6.1.4-1 ensures that the resistance of longitudinal stiffeners will not be impacted by local

$$\frac{b}{t} \leq \lambda_r \quad (\text{E6.1.4-1})$$

where:

- λ_r = corresponding width-to-thickness ratio limit for the longitudinal stiffener plate element under consideration as specified in Table 6.9.4.2.1-1
- b = longitudinal stiffener plate element width as specified in Table 6.9.4.2.1-1 (in.)
- t = longitudinal stiffener plate element thickness (in.)

In addition, tee and angle section longitudinal stiffeners should satisfy:

$$\frac{J_s}{I_{ps}} \geq 5.0 \frac{F_y}{E} \quad (\text{E6.1.4-2})$$

where:

- F_y = specified minimum yield strength of the longitudinally stiffened plate element under consideration (ksi)
- J_s = St. Venant torsional constant of the longitudinal stiffener alone, not including the contribution from the stiffened plate (in.⁴)
- I_{ps} = polar moment of inertia of the longitudinal stiffener alone about the attached edge (in.⁴)

buckling of the stiffener cross-section elements. Eq. E6.1.4-2 ensures against torsional buckling, or tripping, of tee and angle section stiffeners about the edge of the stiffener attached to the plate. For flat plate longitudinal stiffeners, these two equations give the same requirement; therefore, only Eq. E6.1.4-1 needs to be checked. Eq. E6.1.4-2 neglects the warping contribution to the torsional resistance, which tends to be small in many practical cases considering the length between the locations of torsional restraint at transverse stiffeners and/or diaphragms.

Satisfaction of Eq. E6.1.4-1 is considered most appropriate for new designs. In cases where Eq. E6.1.4-1 is violated in any cross-section component of longitudinal stiffeners in existing structures, it is recommended that the resistance of the longitudinally stiffened plate specified in Article E6.1.3 should be calculated by using an effective width equal to $\lambda_r t$ within the corresponding longitudinal stiffener cross-section components. For plates of the longitudinal stiffener cross-section supported only on one longitudinal edge, such as flat plate stiffeners and flanges of T-section stiffeners, the effective width, $\lambda_r t$, is placed adjacent to that edge. For plates of the longitudinal stiffener cross-section supported on two longitudinal edges, such as the stem of T-section stiffeners, half of the above effective width is placed adjacent to each edge. This approach gives an appropriate estimate of the influence of slender cross-section elements in longitudinal stiffeners. The use of the traditional approach of substituting a factored longitudinal stress in the stiffener, f_a , due to axial compression and flexure is not recommended. The true stresses in the longitudinal stiffener can easily approach F_y in certain portions of the stiffener length, due to the axial compression plus second-order bending in the stiffener, including the influence of stiffener initial out-of-straightness. The wavelength associated with local buckling of the stiffener cross-section components is typically relatively short, and this can lead to a local failure along the stiffener length that is not captured by simply substituting f_a for F_y within Eq. E6.1.4-1.

Eq. E6.1.4-2 tends to require relatively thick plates for tee and angle stiffeners to ensure that the stiffener does not fail in a mode involving torsional buckling about the connection to the stiffened plate, commonly referred to as tripping. This equation is considered as being most appropriate for new designs. Eq. E6.1.4-2 neglects the potential contribution from the stiffened plate to twisting of the stiffener about its connection to the plate. Quantification of this torsional restraint is a complex problem that has not yet been fully studied (White et al., 2019b).

As discussed above, traditional approaches to conservatively estimate plate local buckling resistances have sometimes replaced F_y in equations for the nonslender plate limit, such as in Eq. E6.1.4-1, by the factored longitudinal compressive stress in the component due to axial force plus bending within the

Longitudinal stiffeners on flanges with $b_{sp}/t_{sp} > 90$ generally shall satisfy:

$$a/r_s \leq 120 \quad (\text{E6.1.4-3})$$

in which:

r_s = radius of gyration of the stiffener strut about an axis parallel to the plane of the stiffened plate (in.)

$$= \sqrt{I_s/A_{gs}} \quad (\text{E6.1.4-4})$$

where:

a = longitudinal spacing between locations of transverse stiffeners or diaphragms that provide transverse lateral restraint to the longitudinally stiffened plate under consideration (in.)

b_{sp} = total width of the longitudinally stiffened plate, taken as the inside distance between the plates providing lateral restraint to its longitudinal edges (in.)

A_{gs} = gross area of an individual stiffener strut as defined in Article E6.1.3 (in.²)

I_s = moment of inertia of an individual stiffener strut as defined in Article E6.1.3 (in.⁴)

t_{sp} = thickness of the longitudinally stiffened plate under consideration (in.)

E6.1.5—Transverse Stiffeners

E6.1.5.1—General

Transverse stiffeners provided to enhance the resistance of a longitudinally stiffened plate should consist of a flat rectangular plate or a T-section continuously welded to one side of the stiffened plate, or a top or bottom strut of an internal cross-frame or a wide-flange section placed across the outstanding end of the longitudinal stiffeners.

structural member, f_a . The tripping limit state for an open-section longitudinal stiffener is a different problem than local buckling of a flat plate. As a coarse relaxed estimate of the requirement in Eq. E6.1.4-2, to avoid tripping, and until further research can be conducted to better ascertain an improved estimate of the tripping resistance, it is recommended that F_y in this equation may be replaced by the average between the stiffener specified minimum yield strength, F_y , and the maximum factored longitudinal stress in the stiffener, f_a . The use of the factored longitudinal stress in this way as a modified stiffener tripping check is considered sufficient because of the long buckling length associated with the tripping limit state. White et al. (2019b) discuss a number of potential alternative methods for verifying the torsional stability of open-section longitudinal stiffeners.

The limit $a/r_s \leq 120$ on longitudinally stiffened flange plates ensures against excessive out-of-plane deflection of a stiffened plate under its self-weight plus a small transverse concentrated load (White et al., 2019a). This limit is applied regardless of whether or not the member is in a horizontal configuration in the final constructed geometry, to limit such deflections with the member oriented horizontally during construction operations. This limit need not be satisfied for flanges with $b_{sp}/t_{sp} \leq 90$ since the out-of-plane deformations due to the above load effects tend to be small in these cases without consideration of the longitudinal stiffening.

CE6.1.5.1

The provisions contained herein apply for the design of transverse stiffeners that are provided to enhance the resistance of a longitudinally stiffened plate subjected to a net axial compression within the plate, with or without flexure within the plane of the plate.

With the exception of longitudinally stiffened plates containing transverse stiffeners in which:

- the characteristic length, ℓ_c , from Eq. E6.1.3-8 is less than the spacing, a , defined in Article E6.1.3, and;
- the transverse stiffeners are not subjected to any directly applied bending or axial compression,

transverse stiffeners used to increase the compressive resistance of a longitudinally stiffened plate shall satisfy the moment of inertia requirements specified in Article E6.1.5.2.

Transverse stiffeners generally should have a moment of inertia, I_t , defined in Article E6.1.5.2 greater than or equal to the moment of inertia of the longitudinal stiffeners, I_s , defined in Article E6.1.3.

The cross-section elements of transverse stiffeners also should satisfy the requirements of Eqs. E6.1.4-1 and E6.1.4-2.

For longitudinally stiffened plates containing transverse stiffeners that satisfy both situations specified herein, the transverse stiffeners do not serve any purpose to enhance the axial compressive resistance of the longitudinally stiffened plate, and, any potential destabilization of the transverse stiffeners from the longitudinal compression in the plate is not a consideration. Therefore, in these cases, the moment of inertia requirements of Article E6.1.5.2 may be waived.

The provisions contained herein do not apply for cases where the transverse stiffener is subjected to a concentrically applied axial compressive force, and/or directly applied loads causing bending of the stiffener, whether or not the characteristic length, ℓ_c , is less than the spacing a . White et al. (2019b) discuss example cases where this may potentially occur, including top or bottom struts of internal cross-frames that serve as transverse stiffeners to enhance the resistance of the longitudinally stiffened plate, and provide an alternative moment of inertia requirement to handle such cases.

The minimum requirement that the transverse stiffener moment of inertia, I_t , be greater than or equal to the moment of inertia, I_s , of the longitudinal stiffeners, combined with the requirement from Eq. E6.1.4-3, helps ensure against excessive out-of-plane deflection of a stiffened plate under its self-weight plus a small transverse concentrated load in cases where the calculated axial compression in the plate is small, and therefore the requirements from Eqs. E6.1.5.2-1 and E6.1.5.2-2 are small (White et al., 2019a). One example of this situation is a case where transverse stiffeners are installed to serve only as points of termination of longitudinal stiffeners in a tension zone. In designs where b_{sp}/a_{max} is close to or greater than 1.0, where b_{sp} is the total width of the stiffened plate as defined in Article E6.1.4 and a_{max} is the largest of the longitudinal spacings to the adjacent transverse stiffeners or diaphragms providing lateral restraint to the plate, I_t may need to be larger than I_s to satisfy out-of-plane deflection criteria under service loads (White et al., 2019a).

Transverse stiffeners should also satisfy Eqs. E6.1.4-1 and E6.1.4-2 to avoid potential local buckling of the elements of the stiffener, as well as torsional buckling, or tripping, of T-section stiffeners about the edge of the stiffener attached to the plate. These requirements are easily satisfied by flat plate transverse stiffeners, and as noted in Article CE6.1.4, Eqs. E6.1.4-1 and E6.1.4-2 are equivalent for these stiffener types. However, Eq. E6.1.4-2 can be prohibitive for larger transverse stiffeners containing flange elements, such as T-sections, in large box-section members. In these cases, the transverse stiffeners should be designed less conservatively by considering them explicitly as beam-column or beam members subjected to the axial force and/or bending moment induced in the stiffener, as discussed further in White et al. (2019b).

Longitudinal stiffeners shall be structurally continuous at transverse stiffeners. Transverse stiffeners also shall be structurally continuous and attached at their ends to the plates providing lateral restraint to the edge of the longitudinally stiffened plate under consideration.

Longitudinal stiffeners must be structurally continuous at any transverse stiffeners. Cutouts may be placed in the transverse stiffeners to accommodate the continuous longitudinal stiffeners. Alternatively, a top or bottom strut of an internal cross-frame, or a wide-flange section, satisfying the requirements specified herein may serve as a transverse stiffener and be placed across the outstanding end of the longitudinal stiffeners. In either case, the longitudinal stiffeners should be attached to the transverse stiffeners. T-section longitudinal stiffeners may be conveniently attached to the transverse stiffeners by welds or bolts with a pair of clip angles. A welded tab plate may also be used to attach the stiffeners.

Alternatively, transverse stiffeners that are welded to the stiffened plate may be discontinued and welded to the continuous longitudinal stiffeners such that they act as continuous elements across the longitudinal stiffeners as shown in Table 6.6.1.2.4-1.

In all cases, the attachment of a longitudinal stiffener to the transverse stiffener should be designed for the following force perpendicular to the plane of the stiffened plate:

$$V_{ut} = 0.01P_{ups} + V_{ut1} \quad (\text{CE6.1.5.1-1})$$

where:

- P_{ups} = factored axial force within the longitudinal stiffener strut under consideration, composed of the longitudinal stiffener and the tributary plate width, determined from a structural analysis considering the gross cross-section (kip)
- V_{ut1} = first-order force transferred by the attachment due to any directly applied factored loads on the longitudinal stiffener perpendicular to the plane of the stiffened plate, as applicable (kip)

The attachment at the ends of a transverse stiffener should be designed to transmit the following force perpendicular to the plane of the stiffened plate:

$$V_{ut} = 0.005P_{up} \left(\frac{b_{sp}}{a} \right) + 0.01P_{ut} + V_{ut1} \quad (\text{CE6.1.5.1-2})$$

where a , b_{sp} , and P_{up} are defined in Article E6.1.5.2, P_{ut} is the direct factored axial compression force in the transverse stiffener, as applicable, and:

- V_{ut1} = first-order force in the direction perpendicular to the plane of the stiffened plate at the attachment due to any directly applied factored loads, as applicable (kip)

E6.1.5.2—Moment of Inertia

Transverse stiffeners that are:

- used to strengthen a longitudinally stiffened plate, and

CE6.1.5.2

Eq. E6.1.5.2-1 ensures adequate lateral stiffness to resist the destabilizing load effects from the factored longitudinal compression force in the stiffened plate, including the effects from the longitudinal stiffeners. In

- are not subjected to a concentrically applied axial compressive force and/or directly applied loads causing bending of the stiffener,

shall satisfy the following moment of inertia requirements:

$$I_t \geq 0.05 \frac{P_{up}}{a_{min}} \frac{b_{sp}^3}{E} \quad (\text{E6.1.5.2-1})$$

and

$$I_t \geq \left(0.0009 \frac{E}{F_y} \frac{c}{b_{sp}} + 0.02 \right) \frac{P_{up}}{a_{min}} \frac{b_{sp}^3}{E} \quad (\text{E6.1.5.2-2})$$

where:

- a_{min} = smallest of the longitudinal spacings to the adjacent transverse stiffeners or diaphragms providing lateral restraint to the plate (in.)
- c = largest distance from the neutral axis to the extreme fiber of the transverse stiffener considered in the calculation of I_t (in.)
- b_{sp} = total inside width between the plate elements providing lateral restraint to the longitudinal edges of the plate under consideration (in.)
- F_y = smallest specified minimum yield strength of the stiffened plate and the transverse stiffener under consideration (ksi)
- I_t = moment of inertia of the transverse stiffener, including a width of the stiffened plate equal to $9t_{sp}$, but not more than the actual dimension available, on each side of the stiffener avoiding any overlap with contributing parts to adjacent stiffeners or diaphragms, taken about the centroidal axis of the combined section. The reduced cross-section at cutouts to accommodate longitudinal stiffeners shall be considered; the smallest moment of inertia at such cutouts shall be used for I_t (in.⁴)
- P_{up} = total factored longitudinal compression force in the plate under consideration, determined from a structural analysis considering the gross cross-section, including the longitudinal stiffeners, and including all sources of factored longitudinal normal compressive stresses from axial loading and from flexure; in cases where the plate is subjected to longitudinal normal stresses in tension over a portion of its width, the tensile stresses shall be neglected in determining this force (kip)
- t_{sp} = thickness of the stiffened plate (in.)

many situations, the factored longitudinal compression force in the stiffened plate, quantified by the term P_{up} , provides the only significant demand on the transverse stiffeners.

Eq. E6.1.5.2-2 is an indirect moment of inertia requirement necessary to ensure that the transverse stiffeners have adequate lateral strength to resist the destabilizing load effects from the factored longitudinal compression force in the plate, including the effects from the longitudinal stiffeners. Alternatively, Eq. E6.1.5.2-2 may be expressed as the following general requirement on c , given a provided moment of inertia, I_t , to avoid early yielding of the stiffener:

$$c \leq 1,200 \frac{F_y}{E} \left(\frac{I_t}{\frac{P_{up}}{a_{min}} \frac{b_{sp}^3}{E}} - \frac{2}{\pi^4} \right) b_{sp} \quad (\text{CE6.1.5.2-1})$$

The moment of inertia of the transverse stiffener is commonly calculated assuming a width of the stiffened plate equal to $9t_{sp}$ on each side of the stiffener as a flange contribution from the plate, as stated in the definition for I_t . However, a width of $b_{sp}/10$, or a total width of $b_{sp}/5$, may be more appropriate and may be used. This width is based on the consideration of shear lag for the plate acting as a flange of the transverse stiffener. The width $9t_{sp}$ is recommended within these provisions as a conservative value for one-half of this flange width, recognizing that there may be some reduction in the effectiveness of the plate acting as a flange of the transverse stiffener due to high normal or shear stresses from other actions in the plate. Either of the above values for the width of the plate contributing to the moment of inertia of the transverse stiffener is limited by the actual dimension available on each side of the stiffener, avoiding any overlap with contributing parts to adjacent stiffeners or diaphragms.

SECTION 7

ALUMINUM STRUCTURES

Commentary is opposite the text it annotates.

7.1—SCOPE

C7.1

This Section covers the design of aluminum components and connections for beam and girder structures, and metal deck systems. Horizontally curved girders and non-redundant structures are not addressed.

In highway bridges, aluminum is usually used in conjunction with other materials such as steel or concrete. This Section addresses the design of the aluminum components; the Designer should use other Sections for the design of components of other materials.

Many of the provisions in this Section are based on the *Specification for Aluminum Structures*, published by the Aluminum Association as Part I of the 2015 *Aluminum Design Manual* (AA, 2015).

7.2—DEFINITIONS

The provisions of Article 6.2 apply to terms used in this Section that are not defined below.

Beam—A structural member whose primary function is to transmit loads to the support primarily through flexure and shear.

Clear Distance of Bolts—The distance between the edges of adjacent bolt holes.

Closed Shape—A hollow shape that resists lateral-torsional buckling primarily by torsional resistance rather than warping resistance.

Column—A structural member that has the primary function of resisting a compressive axial force.

Element—A part of a shape's cross-section that is rectangular in cross-section or of constant curvature and thickness. Elements are connected to other elements only along their longitudinal edges. An I-beam, for example, consists of five elements, which include a web element and two elements in each flange.

Longitudinal Weld—A weld whose axis is parallel to the member's length axis.

Plate—A flat, rolled product whose thickness equals or exceeds 0.250 in.

Transverse Weld—A weld whose axis is perpendicular to the member's length axis.

Weld-Affected Zone—Material within 1.0 in. of the centerline of a weld.

7.3—NOTATION

$(ADTT)_{SL}$ = single lane ADTT as specified in Article 3.6.1.4.2 (7.6.2.5)

A_e = effective net area of the member (in.²) (7.8.2.1)

A_f = area of the member farther than $2c/3$ from the neutral axis, where c is the distance from the neutral axis to the extreme compression fiber (in.²) (7.10.4)

A_g = gross cross-sectional area (in.²) (7.5.4.4.1)

A_{gc} = gross area of the element in compression (in.²) (7.5.4.5.1)

A_{gt} = gross area in tension (in.²) (7.12.4)

A_{gv} = gross area in shear (in.²); gross area of the connection element subject to shear (in.²) (7.12.4) (7.12.5.3)

A_i = area of element i (in.²) (7.9.2.2.2)

A_L = cross-sectional area of the longitudinal stiffener (in.²) (7.5.4.5.4)

A_n = net area of the web (in.²); net area of the pipe or tube (in.²); net area of the member at the connection (in.²) (7.5.4.6.2) (7.5.4.6.4) (7.8.2.2)

A_{nt} = net area in tension (in.²) (7.12.4)

A_{nv} = net area in shear (in.²); net area of the connection element subject to shear (in.²) (7.12.4) (7.12.5.3)

A_s = area of the stiffener (in.²) (7.5.4.4.5)

A_v = shear area (in.²) (7.5.4.6.1)

A_w = area of the web (in.²) (7.5.4.6.2)

A_{wz}	=	cross-sectional area of the weld-affected zone (in. ²); weld-affected area of the web (in. ²); weld-affected area of the pipe or tube (in. ²); weld-affected area of the member farther than $2c/3$ from the neutral axis, where c is the distance from the neutral axis to the extreme compression fiber (in. ²) (7.5.4.4.1) (7.5.4.6.2) (7.5.4.6.4) (7.10.4)
A_{wzc}	=	cross-sectional area of the weld-affected zone in compression (in. ²) (7.5.4.5.1)
a_1	=	the lesser of the clear height of the web and the distance between stiffeners (in.) (7.5.4.6.2)
a_2	=	the greater of the clear height of the web and the distance between stiffeners (in.) (7.5.4.6.2)
B	=	buckling constant intercept (ksi) (7.5.4.3)
b	=	clear height of web (in.); clear height of the web for webs without transverse stiffeners (in.); distance from the unsupported edge to the mid-thickness of the supporting element (in.) (7.5.4.5.4) (7.5.4.6.2) (7.5.4.6.3)
C	=	buckling constant intersection (7.5.4.3)
C_b	=	bending coefficient (7.10.4.1)
C_f	=	constant taken from Table 7.6.2.5-1 (ksi) (7.6.2.5)
C_w	=	warping constant (in. ⁶) (7.9.2.1.3)
C_{wa}	=	web crippling parameter (7.11.2.1)
C_{wb}	=	web crippling parameter (7.11.2.1)
c	=	distance from the neutral axis to the extreme compression fiber (in.) (7.10.4)
c_c	=	distance from neutral axis to the element extreme fiber with the greatest compressive stress (in.) (7.5.4.5.2)
c_{cf}	=	distance from the centerline of a uniform compression element to the cross-section's neutral axis (in.) (7.10.3.1)
c_{cs}	=	distance from the cross-section's neutral axis to the extreme fiber of uniform compression element (in.) (7.10.3.1)
c_{cw}	=	distance from a flexural compression element's extreme compression fiber to the cross-section's neutral axis (in.) (7.10.3.1)
c_o	=	distance from neutral axis to other extreme fiber of the element (in.) (7.5.4.5.2)
D	=	buckling constant slope (ksi); nominal diameter of the bolt (in.); nominal diameter of the pin (in.) (7.5.4.3) (7.12.2.9) (7.12.7.4)
D_s	=	clear length of the stiffener (in.) (7.5.4.4.4)
d	=	full depth of the section (in.); depth of the beam (in.); dimension of the bar in the plane of flexure (in.); member depth (in.) (7.5.4.6.2) (7.10.4.2.1) (7.10.4.2.4) (7.11.2.1)
d_e	=	distance from the center of the bolt to the edge of the part in the direction of force (in.); distance from the center of the pin to the edge of the part in the direction of force (in.) (7.12.2.9) (7.12.7.6)
d_f	=	the distance between the flange centroids; for tees, d_f is the distance between the flange centroid and the tip of the stem (in.) (7.10.4.2.5)
d_s	=	the stiffener's flat width (in.) (7.5.4.4.4)
d_1	=	distance from the neutral axis to the compression flange (in.) (7.5.4.5.4)
E	=	modulus of elasticity (ksi) (7.4.1)
F_b	=	stress corresponding to the resistance of an element in flexural compression (ksi) (7.10.3.1)
F_c	=	compressive buckling stress (ksi); stress corresponding to the resistance of an element in uniform compression (ksi) (7.9.2.1.1) (7.10.3.1)
F_{cy}	=	compressive yield strength (ksi) (7.4.1)
F_e	=	elastic local buckling stress of the cross-section determined by rational analysis (ksi); elastic buckling stress (ksi) (7.5.4.4.7) (7.5.4.7)
F_{nb}	=	stress corresponding to the flexural resistance of elements (ksi) (7.5.4.5.1)
F_{nbo}	=	stress corresponding to the flexural compressive resistance calculated using Articles 7.5.4.5.2 through 7.5.4.5.4 for an element if no part of the cross-section is weld-affected (ksi) (7.5.4.5.1)
F_{nbw}	=	stress corresponding to the flexural compressive resistance calculated using Articles 7.5.4.5.2 through 7.5.4.5.4 for an element if the entire cross-section is weld-affected (ksi) (7.5.4.5.1)
F_{nc}	=	stress corresponding to the uniform compression resistance of elements (ksi) (7.5.4.4.1)
F_{nci}	=	nominal local buckling resistance of element i computed per Articles 7.5.4.4.1 through 7.5.4.4.6 (ksi) (7.9.2.2.2)
F_{nco}	=	stress corresponding to the uniform compression resistance calculated using Articles 7.5.4.4.2 through 7.5.4.4.6 for an element if no part of the cross-section is weld-affected (ksi) (7.5.4.4.1)
F_{ncw}	=	stress corresponding to the uniform compression resistance calculated using Articles 7.5.4.4.2 through 7.5.4.4.6 for an element if the entire cross-section is weld-affected (ksi) (7.5.4.4.1)

F_{ns0}	=	shear stress corresponding to the shear resistance for an element if no part of the cross-section is weld-affected (ksi) (7.5.4.6.1)
F_{nST}	=	stress corresponding to the uniform compression resistance calculated in Article 7.5.4.4.4 (ksi) (7.5.4.4.4)
F_{nsW}	=	shear stress corresponding to the shear resistance for an element if the entire cross-section is weld-affected (ksi) (7.5.4.6.1)
F_{nUT}	=	stress corresponding to the uniform compression resistance calculated using Article 7.5.4.4.2 (ksi) (7.5.4.4.4)
F_{su}	=	shear ultimate strength (ksi); shear ultimate strength of the connection element (ksi) (7.4.1) (7.12.5.3) (7.12.7.4)
F_{suw}	=	shear ultimate strength in the weld-affected zone (ksi); lesser of the welded shear ultimate strengths of the base metals and the filler (ksi); shear ultimate strength of the filler taken as $0.5F_{tuw}$ (ksi); welded shear ultimate strength of the base metal (ksi) (7.5.4.6.1) (7.12.3.2.2b) (7.12.3.2.3b)
F_{sw}	=	fillet weld strength (kips/in.) (7.12.3.2.4)
F_{sy}	=	shear yield strength (ksi); shear yield strength of the connection element; shear yield strength of the pin (7.4.1) (7.12.5.3) (7.12.7.4)
F_{syw}	=	shear yield strength in the weld-affected zone (ksi) (7.12.5.3)
F_{tu}	=	specified minimum tensile ultimate strength (ksi); tensile ultimate strength of the connected part (ksi); tensile ultimate strength of the pin (7.4.1) (7.12.2.9) (7.12.7.5)
F_{tuw}	=	tensile ultimate strength in the weld-affected zone (ksi); lesser of the welded tensile strengths of the base metals and the filler (ksi); tensile ultimate strength of the filler (ksi) (7.4.1) (7.12.3.2.2a) (7.12.3.2.3a)
F_{ty}	=	specified minimum tensile yield strength (ksi) (7.4.1)
F_{tyw}	=	tensile yield strength in the weld-affected zone (ksi) (7.4.1)
$F_{tyw6061}$	=	tensile yield strength in the weld-affected zone of 6061 (ksi) (7.4.1)
f	=	compressive stress at the toe of the flange (ksi) (7.5.4.5.4)
G	=	shear modulus of elasticity (ksi) (7.4.1)
g	=	transverse center-to-center distance (gauge) between two holes (in.) (7.8.3)
g_0	=	distance from the shear center to the point of application of the load (7.10.4.2.5)
I_f	=	moment of inertia of the uniform stress elements about the cross-section's neutral axis (7.10.3.1)
I_L	=	moment of inertia of the longitudinal stiffener about the web of the beam (in. ⁴) (7.5.4.5.4)
I_o	=	moment of inertia of a section comprising the stiffener and one half of the width of the adjacent subelements and the transition corners between them taken about the centroidal axis of the section parallel to the stiffened element (in. ⁴) (7.5.4.4.5)
I_s	=	moment of inertia of transverse stiffener (in. ⁴) (7.5.4.6.2)
I_w	=	moment of inertia of the flexural compression elements about the cross-section's neutral axis (in. ⁴) (7.10.3.1)
I_x	=	moment of inertia about the strong axis (in. ⁴) (7.9.2.1.3)
I_y	=	moment of inertia about the weak axis (in. ⁴); moment of inertia about the y -axis (in. ⁴) (7.9.2.1.3) (7.10.4.2.1)
I_{yc}	=	moment of inertia of the compression flange about the y -axis (in. ³) (7.10.4.2.5)
J	=	torsion constant (in. ⁴) (7.10.4.2)
K	=	effective length factor specified in Article 4.6.2.5 (7.9.2.1.1)
k_1	=	postbuckling constant (7.5.4.3)
k_2	=	postbuckling constant (7.5.4.3)
L	=	member length (in.) (7.9.2.1.1)
L_b	=	unbraced length (in.) (7.10.4.2.1)
L_v	=	length of tube from maximum to zero shear force (in.) (7.5.4.6.4)
l	=	unbraced length (in.) (7.8.4)
M_A	=	absolute value of the moment at the quarter point of the unbraced segment (kip-in.) (7.10.4.1.1)
M_B	=	absolute value of the moment at the midpoint of the unbraced segment (kip-in.) (7.10.4.1.1)
M_C	=	absolute value of the moment at the three-quarter point of the unbraced segment (kip-in.) (7.10.4.1.1)
M_e	=	elastic lateral-torsional buckling moment determined by analysis (7.10.4.2.5)
M_{max}	=	absolute value of the maximum moment in the unbraced segment (kip-in.) (7.10.4.1.1)
M_n	=	nominal flexural resistance of the pin (7.12.7.1)
M_{rx}	=	factored flexural resistance about the major principal axis (kip-in.) (7.8.2.3)
M_{ry}	=	factored flexural resistance about the minor principal axis (kip-in.) (7.8.2.3)
M_u	=	moment in the member at the location of the concentrated force resulting from factored loads (kip-in.); moment on the pin due to the factored loads (k-in) (7.11.2.3) (7.12.7.7)

M_{ux}	=	moment about the major principal axis resulting from the factored loads (kip-in.) (7.8.2.3)
M_{uy}	=	moment about the minor principal axis resulting from the factored loads (kip-in.) (7.8.2.3)
m	=	factor for determining the flexural compressive resistance of flat elements; constant taken from Table 7.6.2.5-1 (7.5.4.5.2) (7.6.2.5)
N	=	length of the bearing surface at the concentrated force (in.) (7.11.2.1)
n	=	number of stress range cycles per truck taken from Table 6.6.1.2.5-1 (7.6.2.5)
P_n	=	nominal axial compressive resistance (kip) (7.9.2)
P_{no}	=	nominal member buckling resistance if no part of the cross-section is weld-affected (kip) (7.9.2.1.1)
P_{nu}	=	nominal resistance for tensile rupture (kip) (7.8.2.1)
P_{nw}	=	nominal member buckling resistance if the entire cross-section is weld-affected (kip) (7.9.2.1.1)
P_{ny}	=	nominal resistance for tensile yield (kip) (7.8.2.1)
P_{rc}	=	factored axial compression resistance (kip) (7.9.2)
P_{rt}	=	factored axial tension resistance (kip) (7.8.2.1)
P_u	=	shear force on the pin due to the factored loads (kip) (7.12.7.7)
P_{uc}	=	axial compression resulting from the factored loads (kip) (7.9.4)
P_{ut}	=	axial tension resulting from the factored loads (kip) (7.8.2.3)
R	=	transition radius of an attachment (in.) (7.6.2.3)
R_b	=	mid-thickness radius of a round tube or maximum mid-thickness radius of oval tube (in.) (7.5.4.4.6)
R_i	=	for extruded shapes, $R_i = 0$; for all other shapes, R_i = inside bend radius at the juncture of the flange and web (in.) (7.11.2.1)
R_n	=	nominal resistance to a concentrated force (kip); nominal resistance of a bolt, connection, or connected material (kip); nominal shear resistance of the pin (kip) (7.11.2.1) (7.12.2.2) (7.12.7.7)
R_r	=	factored resistance to a concentrated force (kip); factored resistance of a bolt, connection, or connected material (kip); nominal shear resistance of the pin or connected material (7.11.2.1) (7.12.3.2.2a) (7.12.7.1)
R_S	=	ratio of minimum stress to maximum stress (7.6.2.3)
R_u	=	concentrated force resulting from factored loads (kip) (7.11.2.3)
r	=	radius of gyration (in.) (7.8.4)
r_s	=	the stiffener's radius of gyration about the stiffened element's mid-thickness (in.) (7.5.4.4.4)
r_x	=	major axis radius of gyration (in.) (7.9.2.1.3)
r_y	=	minor axis radius of gyration (in.) (7.9.2.1.3)
r_{ye}	=	effective minor axis radius of gyration (in.) (7.10.4.2.1)
r_0	=	polar radius of gyration about the shear center (in.) (7.9.2.1.3)
S_c	=	section modulus on the compression side of the neutral axis (in. ³) (7.10.2)
S_t	=	section modulus on the tension side of the neutral axis (in. ³) (7.10.2)
S_w	=	fillet weld size (in.) (7.12.3.2.4)
S_x	=	section modulus about the x-axis (in. ³) (7.10.4.2.1)
s	=	distance between transverse stiffeners (in.); longitudinal center-to-center distance (pitch) between two holes (in.) (7.5.4.5.4) (7.8.3)
T_n	=	nominal tensile resistance of bolt (kip) (7.12.2.2)
T_r	=	factored tensile resistance of bolt (kip) (7.12.2.2)
t	=	thickness of web, tube, or pin-connected part (in.); dimension of the bar perpendicular to the plane of flexure (in.); for plain holes, thickness of the connected part; for countersunk holes, thickness of the connected part less ½ the countersink depth (in.) (7.4.1) (7.10.4.2.4) (7.12.2.9)
U	=	reduction factor to account for shear lag taken as given in Article 6.8.2.1 (7.8.2.2)
V	=	shear force on the web at the transverse stiffener (kip) (7.5.4.6.2)
V_n	=	nominal shear resistance (kip) (7.5.4.6.1)
x_0	=	x-coordinate of the shear center with respect to the centroid (in.) (7.9.2.1.3)
y_0	=	y-coordinate of the shear center with respect to the centroid (in.); the shear center's y-coordinate (in.) (7.9.2.1.3) (7.10.4.2.5)
Z	=	plastic modulus (in. ³) (7.10.2)
α	=	thermal coefficient of expansion (in./in./°F) (7.4.1)
α_s	=	factor for a longitudinal web stiffener (7.5.4.5.4)
γ	=	load factor specified in Table 3.4.1-1 for the fatigue load combination (7.6.2.2)
$(\Delta F)_n$	=	nominal fatigue resistance as specified in Article 7.6.2.5 (ksi) (7.6.2.2)
$(\Delta F)_{TH}$	=	constant amplitude threshold taken from Table 7.6.2.5-1 (ksi) (7.6.2.5)

- (Δf) = force effect, live load stress range due to the passage of the fatigue load as specified in Article 3.6.1.4 (ksi) (7.6.2.2)
- θ_s = angle between the stiffener and the stiffened element (7.5.4.4.4)
- θ_w = angle between the plane of web and the plane of the bearing surface ($\theta_w \leq 90^\circ$) (7.11.2.1)
- λ = axial slenderness ratio; lateral torsional buckling slenderness (7.9.2.1.1) (7.10.4)
- λ_e = slenderness boundary for the effectiveness of edge stiffeners (7.5.4.4.4)
- λ_{eq} = slenderness ratio of a shape corresponding to the elastic local buckling stress (7.5.4.4.7)

7.4—MATERIALS

7.4.1—Aluminum Alloys

Aluminum extrusions shall conform to the requirements of Table 7.4.1-1. Aluminum sheet and plate shall conform to the requirements of Table 7.4.1-2. Design shall be based on the strength and stiffness properties given in Tables 7.4.1-1, 7.4.1-2, and 7.4.1-3. For 6061 parts of any thickness welded with 5183, 5356, or 5556 filler and parts 0.375 in. thick or less when welded with 4043 filler, $F_{tys6061}$ shall be taken as 15 ksi; for 6061 parts thicker than 0.375 in. when welded with 4043 filler, $F_{tys6061}$ shall be taken as 11 ksi.

C7.4.1

The strengths given in Tables 7.4.1-1 and 7.4.1-2 are:

- The specified minimum tensile ultimate strength, F_{tu} , and the tensile yield strength, F_{ty} , are the minimum strengths specified in ASTM B209, B221, and B928.
- The welded minimum tensile ultimate strength F_{tws} is the qualification strength required by AWS D1.2/D1.2M, *Structural Welding Code—Aluminum* (AWS, 2014), hereafter referred to as “AWS D1.2/D1.2M.”
- The welded tensile yield strength, F_{tys} , is taken from the *Aluminum Design Manual* (AA, 2015).

The modulus of elasticity and coefficient of thermal expansion vary slightly among aluminum alloys; the values given here are conservative. The relationship between shear yield strength and tensile yield strength and between shear ultimate strength and tensile ultimate strength are based on the von Mises yield criterion.

Some aluminum alloys are notch-sensitive, and in the *Aluminum Design Manual* (AA, 2015) their tensile rupture strengths are divided by a tension coefficient, k_t , which is greater than one. The aluminum alloys included in Tables 7.4.1-1 and 7.4.1-2 are not notch-sensitive, and therefore, for these alloys, k_t is 1, and thus the k_t factor is not included in the expressions for tensile strength given in this Specification. Aluminum castings are not included in this Specification because their fatigue strengths have not been established and their use in highway bridges is rare.

The properties given in Article 7.4.1 apply to material held at temperatures of 200°F or less for any period of time. Aluminum's strength and modulus of elasticity decrease at temperatures above 200°F, and the decrease in strength remains after returning to ambient temperature after heating above 200°F.

Table 7.4.1-1—Minimum Mechanical Properties of Aluminum Extrusions

ASTM Specification	B221	B221	B221	B221	B221	B221
Alloy-Temper	6005A-T61	6061-T6, T6510, T6511	6063-T5	6063-T5	6063-T6	6082-T6, T6511

Modulus of elasticity	E	10,100 ksi
Shear modulus of elasticity	G	3800 ksi
Poisson's ratio	ν	0.33
Thermal coefficient of expansion	α	13×10^{-6} in./in./°F
Compressive yield strength for unwelded tempers beginning with H	F_{cy}	$0.9F_{ty}$
Compressive yield strength for all other material	F_{cy}	F_{ty}
Shear yield strength	F_{sy}	$0.6F_{ty}$
Shear ultimate strength	F_{su}	$0.6F_{tu}$

7.4.2—Pins, Rollers, and Rockers

Pins, rollers, and expansion rockers shall conform to one of the following:

- Steel pins, rollers, and expansion rockers shall conform to Article 6.4.2 and shall be galvanized. Aluminum pins, rollers, and expansion rockers shall conform to Article 7.4.1.

7.4.3—Bolts, Nuts, and Washers

7.4.3.1—Bolts

High-strength bolts used as structural fasteners shall conform to ASTM F3125. The specified minimum tensile strengths of ASTM F3125 bolts shall be taken as specified in Table 6.4.3.1.1-1.

Corrosion-resistant coatings may be applied to Grade A325, F1552, and A490 bolts, as specified in ASTM F3125.

Anchor bolts shall conform to ASTM F1554.
Anchor bolts and nuts shall conform to Article 6.4.3.3.

7.4.3.2—Nuts Used with ASTM F3125 Bolts

Nuts used with ASTM F3125 bolts shall be as listed in ASTM F3125 as recommended or suitable for the bolt.

7.4.3.3—Washers Used with ASTM F3125 Bolts

Hardened washers used with ASTM F3125 bolts shall be as listed in ASTM F3125 as recommended or suitable for the bolts.

7.4.3.4—Direct Tension Indicators

Direct tension indicators (DTIs) conforming to the requirements of ASTM F959 may be used in conjunction with bolts, nuts, and washers. DTIs shall conform to Article 6.4.3.1.4.

7.4.4—Shear Connectors

Shear connectors shall conform to Article 7.4.1 or 7.4.3.

7.4.5—Weld Metal

Weld metal shall meet the requirements of AWS
D1.2/D1.2M.

C7.4.4

Headed aluminum shear studs are not a standard commercial product. Extruded shapes or bolts are typically used to transfer shear instead of studs.

C7.4.5

AWS D1.2/D1.2M requires that weld metal (fillers) meet the requirements of AWS A5.10/A5.10M, *Welding Consumables—Wire Electrodes, Wires, and Rods for Welding Aluminum and Aluminum-Alloys—Classification* (AWS, 2017g).

7.5—LIMIT STATES

7.5.1—General

The structural behavior of components made of aluminum, or aluminum in combination with other materials, shall be investigated for each stage that may be critical during construction, handling, transportation, and erection as well as during the service life of the structure of which they are part.

Structural components shall be proportioned to satisfy the requirements at strength, extreme event, service, and fatigue limit states.

7.5.2—Service Limit State

The provisions of Article 2.5.2.6 shall apply.

7.5.3—Fatigue Limit State

Components shall be investigated for fatigue as specified in Article 7.6.

The fatigue load combinations specified in Table 3.4.1-1 and the fatigue live load specified in Article 3.6.1.4 shall apply.

7.5.4—Strength Limit State

7.5.4.1—General

Strength and stability shall be considered using the applicable strength load combinations specified in Table 3.4.1-1.

7.5.4.2—Resistance Factors

Resistance factors, ϕ , for the strength limit state shall be taken as follows:

- For flexure: tensile rupture $\phi_{ft} = 0.75$
- For flexure: limit states other than rupture $\phi_f = 0.90$
- For shear or torsion rupture $\phi_{vt} = 0.75$
- For shear or torsion: limit states other than rupture $\phi_v = 0.90$
- For axial compression $\phi_c = 0.90$
- For axial tension: rupture $\phi_u = 0.75$
- For axial tension: yield $\phi_y = 0.90$
- For pins bearing on connected parts $\phi_b = 0.75$
- For bolts bearing on connected parts $\phi_{bb} = 0.75$
- For block shear rupture $\phi_{bs} = 0.75$
- For web crippling $\phi_w = 0.80$
- For weld metal and base metal at welds $\phi_e = 0.75$

7.5.4.3—Buckling Constants

Buckling constants B , D , and C shall be determined from Tables 7.5.4.3-1 and 7.5.4.3-2. Postbuckling constants k_1 and k_2 shall be determined from Table 7.5.4.3-3.

C7.5.4.3

Buckling constants are used to determine inelastic buckling strengths of aluminum structural components. Table 7.5.4.3-1 matches Table B.4.1; Table 7.5.4.3-2 matches Table B.4.2; and Table 7.5.4.3-3 matches Table B.4.3 of the *Aluminum Design Manual* (AA, 2015).

T5 and T6 are artificially aged tempers.

Table 7.5.4.3-1—Buckling Constants for Tempers Beginning with H and Weld-Affected Zones of All Tempers

Type of Stress and Member	Intercept B (ksi)	Slope D (ksi)	Intersection C
Member Buckling	$B_c = F_{cy} \left(1 + \left(\frac{F_{cy}}{1000} \right)^{1/2} \right)$	$D_c = \frac{B_c}{20} \left(\frac{6B_c}{E} \right)^{1/2}$	$C_c = \frac{2B_c}{3D_c}$
Axial Compression in Flat Elements	$B_p = F_{cy} \left(1 + \left(\frac{F_{cy}}{440} \right)^{1/3} \right)$	$D_p = \frac{B_p}{20} \left(\frac{6B_p}{E} \right)^{1/2}$	$C_p = \frac{2B_p}{3D_p}$
Axial Compression in Curved Elements	$B_t = F_{cy} \left(1 + \left(\frac{F_{cy}}{6500} \right)^{1/5} \right)$	$D_t = \frac{B_t}{3.7} \left(\frac{B_t}{E} \right)^{1/3}$	C_t ; see Tables 7.4.1-1 and 7.4.1-2
Flexural Compression in Flat Elements	$B_{br} = 1.3F_{cy} \left(1 + \left(\frac{F_{cy}}{340} \right)^{1/3} \right)$	$D_{br} = \frac{B_{br}}{20} \left(\frac{6B_{br}}{E} \right)^{1/2}$	$C_{br} = \frac{2B_{br}}{3D_{br}}$
Flexural Compression in Curved Elements	$B_{tb} = 1.5F_{cy} \left(1 + \left(\frac{F_{cy}}{6500} \right)^{1/5} \right)$	$D_{tb} = \frac{B_{tb}}{2.7} \left(\frac{B_{tb}}{E} \right)^{1/3}$	$C_{tb} = \left(\frac{B_{tb} - B_t}{D_{tb} - D_t} \right)^2$
Shear in Flat Elements	$B_s = F_{sy} \left(1 + \left(\frac{F_{sy}}{240} \right)^{1/3} \right)$	$D_s = \frac{B_s}{20} \left(\frac{6B_s}{E} \right)^{1/2}$	$C_s = \frac{2B_s}{3D_s}$

Table 7.5.4.3-2—Buckling Constants for Tempers Beginning with T5 or T6

Type of Stress and Member	Intercept B (ksi)	Slope D (ksi)	Intersection C
Member Buckling	$B_c = F_{cy} \left(1 + \left(\frac{F_{cy}}{2250} \right)^{1/2} \right)$	$D_c = \frac{B_c}{10} \left(\frac{B_c}{E} \right)^{1/2}$	$C_c = 0.41 \frac{B_c}{D_c}$
Axial Compression in Flat Elements	$B_p = F_{cy} \left(1 + \left(\frac{F_{cy}}{1500} \right)^{1/3} \right)$	$D_p = \frac{B_p}{10} \left(\frac{B_p}{E} \right)^{1/2}$	$C_p = 0.41 \frac{B_p}{D_p}$
Axial Compression in Curved Elements	$B_t = F_{cy} \left(1 + \left(\frac{F_{cy}}{50,000} \right)^{1/5} \right)$	$D_t = \frac{B_t}{4.5} \left(\frac{B_t}{E} \right)^{1/3}$	C_t ; see Tables 7.4.1-1 and 7.4.1-2
Flexural Compression in Flat Elements	$B_{br} = 1.3 F_{cy} \left(1 + \left(\frac{F_{cy}}{340} \right)^{1/3} \right)$	$D_{br} = \frac{B_{br}}{20} \left(\frac{6 B_{br}}{E} \right)^{1/2}$	$C_{br} = \frac{2 B_{br}}{3 D_{br}}$
Flexural Compression in Curved Elements	$B_{tb} = 1.5 F_{cy} \left(1 + \left(\frac{F_{cy}}{50,000} \right)^{1/5} \right)$	$D_{tb} = \frac{B_{tb}}{2.7} \left(\frac{B_{tb}}{E} \right)^{1/3}$	$C_{tb} = \left(\frac{B_{tb} - B_t}{D_{tb} - D_t} \right)^2$
Shear in Flat Elements	$B_s = F_{sy} \left(1 + \left(\frac{F_{sy}}{800} \right)^{1/3} \right)$	$D_s = \frac{B_s}{10} \left(\frac{B_s}{E} \right)^{1/2}$	$C_s = 0.41 \frac{B_s}{D_s}$

Table 7.5.4.3-3—Postbuckling Constants for Flat Elements

Type of Element	k_1	k_2
Flat Elements in Axial Compression for Temper Designations Beginning with H, and Weld-Affected Zones of All Tempers	0.50	2.04
Flat Elements in Axial Compression for Temper Designations Beginning with T5 or T6	0.35	2.27
Flat Elements in Flexure	0.50	2.04

7.5.4.4—Nominal Resistance of Elements in Uniform Compression

7.5.4.4.1—General

The nominal resistance of elements in uniform compression shall be taken as:

- For unwelded elements:

$$F_{nc} = F_{nco} \quad (7.5.4.4.1-1)$$

- For welded elements:

$$F_{nc} = F_{nco}(1 - A_{wz}/A_g) + F_{ncw} A_{wz}/A_g \quad (7.5.4.4.1-2)$$

where:

F_{nco} = stress corresponding to the uniform compression resistance calculated using Articles 7.5.4.4.2 through 7.5.4.4.6 for an element if no part of the cross-section is

C7.5.4.4.1

This Article matches Section B.5.4 of the *Aluminum Design Manual* (AA, 2015).

- F_{ncw} = weld-affected using buckling constants for unwelded metal and unwelded strengths (ksi) stress corresponding to the uniform compression resistance calculated using Articles 7.5.4.4.2 through 7.5.4.4.6 for an element if the entire cross-section is weld-affected using buckling constants for weld-affected zones and welded strengths (ksi). For transversely welded elements with $b/t \leq \lambda_1$, $F_{ncw} = F_{nc}$
- A_{wz} = cross-sectional area of the weld-affected zone (in.²)
- A_g = gross cross-sectional area of the element (in.²)
- λ_1 = slenderness at the intersection of yielding and inelastic buckling

7.5.4.4.2—Flat Elements Supported on One Edge

C7.5.4.4.2

The nominal resistance, F_{nc} , of flat elements supported on one edge shall be taken as:

This Article matches Section B.5.4.1 of the *Aluminum Design Manual* (AA, 2015).

- If $b/t \leq \frac{B_p - F_{cy}}{5.0D_p} = \lambda_1$, then

$$F_{nc} = F_{cy} \quad (7.5.4.4.2-1)$$

- If $\frac{B_p - F_{cy}}{5.0D_p} < b/t < \frac{C_p}{5.0}$, then

$$F_{nc} = B_p - 5.0D_p b/t \quad (7.5.4.4.2-2)$$

- If $b/t \geq \frac{C_p}{5.0}$, then

$$F_{nc} = \frac{\pi^2 E}{(5.0b/t)^2} \quad (7.5.4.4.2-3)$$

where:

B_p , D_p , and C_p = parameters specified in Table 7.5.4.3-1 or 7.5.4.3-2

7.5.4.4.3—Flat Elements Supported on Both Edges

C7.5.4.4.3

The stress, F_{nc} , corresponding to the uniform compression resistance of flat elements supported on both edges shall be taken as:

This Article matches Section B.5.4.2 of the *Aluminum Design Manual* (AA, 2015).

- If $b/t \leq \frac{B_p - F_{cy}}{1.6D_p} = \lambda_1$, then

$$F_{nc} = F_{cy} \quad (7.5.4.4.3-1)$$

- If $\frac{B_p - F_{cy}}{1.6D_p} < b/t < \frac{k_1 B_p}{1.6D_p}$, then

$$F_{nc} = B_p - 1.6D_p b/t \quad (7.5.4.4.3-2)$$

- If $b/t \geq \frac{k_s B_s}{1.6 D_s}$, then

$$F_{nc} = \frac{k_s \sqrt{B_s E}}{1.6 b / t} \quad (7.5.4.4.3-3)$$

7.5.4.4.4—Flat Elements Supported on One Edge and with a Stiffener on the Other Edge

C7.5.4.4.4

For flat elements satisfying all of the following criteria:

This Article matches Section B.5.4.3 of the *Aluminum Design Manual* (AA, 2015).

- supported on one edge and with a stiffener on the other edge,
- with a stiffener of depth $D_s \leq 0.8b$, where D_s is the clear length of the stiffener, and
- with a thickness no greater than the stiffener's thickness,

the nominal resistance shall be taken as:

$$F_{nc} = F_{nUT} + (F_{nST} - F_{nUT}) \rho_{ST} \quad (7.5.4.4.4-1)$$

where:

F_{nUT} is F_{nc} determined using Article 7.5.4.4.2 and neglecting the stiffener.

F_{nST} is F_{nc} determined using Article 7.5.4.4.3.

ρ_{ST} = stiffener effectiveness ratio determined as follows:

- If $b/t \leq \lambda_e/3$, then (7.5.4.4.4-2)
 $\rho_{ST} = 1.0$

- If $\lambda_e/3 < b/t \leq \lambda_e$, then (7.5.4.4.4-3)
$$\rho_{ST} = \frac{r_s}{9t \left(\frac{b/t}{\lambda_e} - \frac{1}{3} \right)} \leq 1.0$$

- If $\lambda_e < b/t \leq 2\lambda_e$, then (7.5.4.4.4-4)
$$\rho_{ST} = \frac{r_s}{1.5t \left(\frac{b/t}{\lambda_e} + 3 \right)} \leq 1.0$$

in which:

$$\lambda_e = 1.28 \sqrt{E / F_{cy}} \quad (7.5.4.4.4-5)$$

where:

r_s = the stiffener's radius of gyration about the stiffened element's mid-thickness

For straight stiffeners of constant thicknesses, r_s may be taken as:

$$r_s = \frac{(d_s \sin \theta_s)}{\sqrt{3}} \quad (7.5.4.4.4-6)$$

where:

d_s = the stiffener's flat width (in.)
 θ_s = the angle between the stiffener and the stiffened element (deg)

F_{nc} for the stiffened element determined using Article 7.5.4.4.4 shall not exceed F_{nc} for the stiffener alone determined using Article 7.5.4.4.2.

For flat elements:

- supported on one edge and with a stiffener on the other edge, and
- with a stiffener of depth $D_S > 0.8b$, where D_S is the clear length of the stiffener, or
- with a thickness greater than the stiffener's thickness.

the nominal resistance shall be taken as:

$$F_{nc} = F_{nUT} \quad (7.5.4.4.4-7)$$

7.5.4.4.5—Flat Elements Supported on Both Edges and with an Intermediate Stiffener

C7.5.4.4.5

The nominal resistance of flat elements supported on both edges and with an intermediate stiffener shall be taken as:

This Article matches Section B.5.4.4 of the *Aluminum Design Manual* (AA, 2015).

- If $\lambda_s \leq \frac{B_c - F_c}{D_c} = \lambda_1$, then

$$F_{nc} = F_{cy} \quad (7.5.4.4.5-1)$$

- If $\frac{B_c - F_{cy}}{D_c} < \lambda_s < C_c$, then

$$F_{nc} = B_c - D_c \lambda_s \quad (7.5.4.4.5-2)$$

- If $\lambda_s \geq C_c$, then

$$F_{nc} = \frac{\pi^2 E}{\lambda_c^2} \quad (7.5.4.4.5-3)$$

in which:

$$\lambda_s = 4.62 \left(\frac{b}{t} \right) \sqrt{\frac{1 + A_s / (bt)}{1 + \sqrt{1 + \frac{10.67 I_e}{br^3}}}} \quad (7.5.4.4.5-4)$$

where:

- A_s = area of the stiffener (in.²)
 I_o = moment of inertia of a section comprising the stiffener and one half of the width of the adjacent subelements and the transition corners between them taken about the centroidal axis of the section parallel to the stiffened element (in.⁴)
 B_e , D_o , and C_e = parameters specified in Table 7.5.4.3-1 or 7.5.4.3-2

F_{nc} shall not exceed F_{nc} determined using Article 7.5.4.4.3 for the sub-elements of the stiffened element.

F_{nc} need not be less than F_{nc} determined using Article 7.5.4.4.3 and neglecting the stiffener.

7.5.4.4.6—Round Hollow Elements and Curved Elements Supported on Both Edges

C7.5.4.4.6

The nominal resistance of round hollow elements and curved elements supported on both edges shall be taken as:

- If $R_b / t \leq \left(\frac{B_t - F_{cy}}{D_t} \right)^2 = \lambda_1$, then

$$F_{nc} = F_{cy} \quad (7.5.4.4.6-1)$$

- If $\left(\frac{B_t - F_{cy}}{D_t} \right)^2 < R_b / t < C_t$, then

$$F_{nc} = B_t - D_t \sqrt{\frac{R_b}{t}} \quad (7.5.4.4.6-2)$$

- If $R_b / t \geq C_t$, then

$$F_{nc} = \frac{\pi^2 E}{16 \left(\frac{R_b}{t} \right) \left(1 + \frac{\sqrt{R_b / t}}{35} \right)^2} \quad (7.5.4.4.6-3)$$

F_{nc} need not be less than that determined using Article 7.5.4.4.3, where b is the length of the curved element.

For tubes with circumferential welds, use of Article 7.5.4.4.6 shall be limited to tubes with $R_b / t \leq 20$.

where:

- R_b = mid-thickness radius of a round tube or maximum mid-thickness radius of oval tube (in.)
 B_t , D_t , and C_t = parameters specified in Table 7.5.4.3-1 or 7.5.4.3-2

This Article matches Section B.5.4.5 of the *Aluminum Design Manual* (AA, 2015), but also permits the strength of curved elements to be no less than the strength of flat elements of the same length.

7.5.4.4.7—Alternative Method for Flat Elements

C7.5.4.4.7

As an alternative to Articles 7.5.4.4.2 through 7.5.4.4.5, the nominal resistance of flat elements without welds in uniform compression may be determined as:

This Article matches Section B.5.4.6 of the *Aluminum Design Manual* (AA, 2015).

- If $\lambda_{eq} \leq \frac{B_p - F_{cy}}{D_p} = \lambda_1$, then

$$F_{nc} = F_{cy} \quad (7.5.4.4.7-1)$$

- If $\frac{B_p - F_{cy}}{D_p} < \lambda_{eq} < \frac{k_1 B_p}{D_p}$, then

$$F_{nc} = B_p - D_p \lambda_{eq} \quad (7.5.4.4.7-2)$$

- If $\lambda_{eq} \geq \frac{k_1 B_p}{D_p}$, then

$$F_{nc} = \frac{k_2 \sqrt{B_p E}}{\lambda_{eq}} \quad (7.5.4.4.7-3)$$

in which:

$$\lambda_{eq} = \pi \sqrt{\frac{E}{F_e}} \quad (7.5.4.4.7-4)$$

where:

F_e = the elastic local buckling stress of the cross-section determined by rational analysis (ksi)

B_p, D_p = parameters specified in Table 7.5.4.3-1 or 7.5.4.3-2

7.5.4.5—Nominal Resistance of Elements in Flexural Compression

7.5.4.5.1—General

C7.5.4.5.1

The nominal resistance of elements in flexural compression shall be taken as:

This Article matches Section B.5.5 of the *Aluminum Design Manual* (AA, 2015).

- For unwelded elements:

$$F_{nb} = F_{nbo} \quad (7.5.4.5.1-1)$$

- For welded elements:

$$F_{nb} = F_{nbo} (1 - A_{wzc}/A_{gc}) + F_{nbw} A_{wzc}/A_{gc} \quad (7.5.4.5.1-2)$$

where:

F_{nbo} = stress corresponding to the flexural compressive resistance calculated using Articles 7.5.4.5.2 through 7.5.4.5.4 for an

element if no part of the cross-section is weld-affected using buckling constants for unwelded metal and unwelded strengths (ksi)

F_{nbw} = stress corresponding to the flexural compressive resistance calculated using Articles 7.5.4.5.2 through 7.5.4.5.4 for an element if the entire cross-section is weld-affected. Use buckling constants for weld-affected zones and welded strengths (ksi).

A_{wzc} = cross-sectional area of the weld-affected zone in compression (in.²)

A_{gc} = gross cross-sectional area of the element in compression (in.²)

7.5.4.5.2—Flat Elements Supported on Both Edges

C7.5.4.5.2

The nominal resistance of flat elements supported on both edges and flat elements supported on the compression edge with the tension edge free shall be taken as:

This Article matches Section B.5.5.1 of the *Aluminum Design Manual* (AA, 2015).

- If $b/t \leq \frac{B_{br} - 1.5F_{cy}}{mD_{br}} = \lambda_1$, then

$$F_{nb} = 1.5F_{cy} \quad (7.5.4.5.2-1)$$

- If $\frac{B_{br} - 1.5F_{cy}}{mD_{br}} < b/t < \frac{k_1 B_{br}}{mD_{br}}$, then

$$F_{nb} = B_{br} - mD_{br}b/t \quad (7.5.4.5.2-2)$$

- If $b/t \geq \frac{k_1 B_{br}}{mD_{br}}$, then

$$F_{nb} = \frac{k_2 \sqrt{B_{br} E}}{(mb/t)} \quad (7.5.4.5.2-3)$$

in which:

m = factor for determining the flexural compressive resistance of flat elements

$m = 1.15 + c_o/(2c_c)$ for $-1 < c_o/c_c < 1$ (7.5.4.5.2-4)

$m = 1.3/(1 - c_o/c_c)$ for $c_o/c_c \leq -1$ (7.5.4.5.2-5)

$m = 0.65$ for $c_c = -c_o$ (7.5.4.5.2-6)

where:

c_c = distance from neutral axis to the element extreme fiber with the greatest compressive stress (in.)

c_o = distance from neutral axis to other extreme fiber of the element (in.)

B_{br}, D_{br} = parameters specified in Table 7.5.4.3-1 or 7.5.4.3-2

Distances to compressive fibers shall be taken as negative and distances to tensile fibers shall be taken as positive.

7.5.4.5.3—Flat Elements Supported on Tension Edge, Compression Edge Free

C7.5.4.5.3

The nominal flexural compressive resistance of flat elements supported on one edge with the compression edge free shall be taken as:

This Article matches Section B.5.5.2 of the *Aluminum Design Manual* (AA, 2015).

- If $b/t \leq \frac{B_{br} - 1.5F_{cy}}{3.5D_{br}} = \lambda_1$, then

$$F_{nb} = 1.5F_{cy} \quad (7.5.4.5.3-1)$$

- If $\frac{B_{br} - 1.5F_{cy}}{3.5D_{br}} < b/t < \frac{C_{br}}{3.5}$, then

$$F_{nb} = B_{br} - 3.5D_{br}b/t \quad (7.5.4.5.3-2)$$

- If $b/t \geq \frac{C_{br}}{3.5}$, then

$$F_{nb} = \frac{\pi^2 E}{(3.5b/t)^2} \quad (7.5.4.5.3-3)$$

7.5.4.5.4—Flat Elements Supported on Both Edges and with a Longitudinal Stiffener

C7.5.4.5.4

The nominal resistance of flat elements supported on both edges and with a longitudinal stiffener located $0.4d_1$ from the supported edge that is in compression shall be taken as:

This Article matches Section B.5.5.3 of the *Aluminum Design Manual* (AA, 2015).

- If $b/t \leq \frac{B_{br} - 1.5F_{cy}}{0.29D_{br}} = \lambda_1$, then

$$F_{nb} = 1.5F_{cy} \quad (7.5.4.5.4-1)$$

- If $\frac{B_{br} - 1.5F_{cy}}{0.29D_{br}} < b/t < \frac{k_1 B_{br}}{0.29D_{br}}$, then

$$F_{nb} = B_{br} - 0.29D_{br}b/t \quad (7.5.4.5.4-2)$$

- If $b/t \geq \frac{k_1 B_{br}}{0.29D_{br}}$, then

$$F_{nb} = \frac{k_2 \sqrt{B_{br} E}}{(0.29b/t)} \quad (7.5.4.5.4-3)$$

The moment of inertia of the longitudinal stiffener, I_L , about the web of the beam shall satisfy:

$$I_L \geq \frac{0.02\alpha_s f t b^3}{E} \left[\left(1 + \frac{6A_L}{bt} \right) \left(\frac{s}{b} \right)^2 + 0.4 \right] \quad (7.5.4.5.4-4)$$

where:

- A_L = cross-sectional area of the longitudinal stiffener (in.²)
- d_1 = distance from the neutral axis to the compression flange (in.)
- f = compressive stress at the toe of the flange (ksi)
- b = clear height of the web (in.)
- s = distance between transverse stiffeners (in.)
- t = web thickness (in.)
- α_s = 1 for a stiffener consisting of equal members on both sides of the web
= 3.5 for a stiffener consisting of a member on only one side of the web

For a stiffener consisting of equal members on both sides of the web, the moment of inertia, I_L , shall be the sum of the moments of inertia about the centerline of the web.

For a stiffener consisting of a member on one side of the web only, the moment of inertia, I_L , shall be taken about the face of the web in contact with the stiffener.

7.5.4.5.5—Pipes and Round Tubes

C7.5.4.5.5

The nominal resistance of round hollow elements and curved elements supported on both edges shall be taken as:

This Article matches Section B.5.5.4 of the *Aluminum Design Manual* (AA, 2015).

- If $R_b / t \leq C_{tb}$, then

$$F_{nb} = B_{tb} - D_{tb} \sqrt{R_b / t} \quad (7.5.4.5.5-1)$$

- If $C_{tb} < R_b / t < C_t$, then

$$F_{nb} = B_t - D_t \sqrt{R_b / t} \quad (7.5.4.5.5-2)$$

- If $R_b / t \geq C_t$, then

$$F_{nb} = \frac{\pi^2 E}{16 \left(\frac{R_b}{t} \right) \left(1 + \frac{\sqrt{R_b / t}}{35} \right)^2} \quad (7.5.4.5.5-3)$$

7.5.4.5.6—Alternative Method for Flat Elements

C7.5.4.5.6

As an alternative to Articles 7.5.4.5.2 through 7.5.4.5.4 for flat elements in flexure without welds, the stress, F_{nb} , may be determined as:

This Article matches Section B.5.5.4 of the *Aluminum Design Manual* (AA, 2015).

- If $\lambda_{eq} \leq \frac{B_p - F_{cy}}{D_p} = \lambda_{c1}$, then

$$F_{nb} = M_{np} S_{xc} \quad (7.5.4.5.6-1)$$

- If $\frac{B_p - F_{cy}}{D_p} < \lambda_{eq} < C_p$, then

$$F_{nb} = \frac{M_{np}}{S_{xc}} - \left(\frac{M_{np}}{S_{xc}} - \frac{\pi^2 E}{C_p^2} \right) \left(\frac{\lambda_{eq} - \lambda_1}{C_p - \lambda_1} \right) \quad (7.5.4.5.6-2)$$

- If $\lambda_{eq} \geq C_p$, then

$$F_{nb} = \frac{k_2 \sqrt{B_p E}}{\lambda_{eq}} \quad (7.5.4.5.6-3)$$

in which:

$$\lambda_{eq} = \pi \sqrt{\frac{E}{F_e}} \quad (7.5.4.5.6-4)$$

where:

F_e = the elastic local buckling stress of the cross-section determined by rational analysis (ksi)

7.5.4.6—Nominal Resistance of Elements in Shear

7.5.4.6.1—General

C7.5.4.6.1

For the limit states of shear yielding and shear buckling, the nominal shear resistance shall be taken as:

This Article matches Section G.1 of the *Aluminum Design Manual* (AA, 2015).

- For unwelded members:

$$V_n = F_{nso} A_v \quad (7.5.4.6.1-1)$$

- For welded members:

$$V_n = F_{nso} (A_v - A_{wz}) + F_{nsw} A_{wz} \quad (7.5.4.6.1-2)$$

where:

F_{nso} = shear stress corresponding to the shear resistance for an element if no part of the cross-section is weld-affected (ksi). Use buckling constants for unwelded metal and unwelded strengths.

F_{nsw} = shear stress corresponding to the shear resistance for an element if the entire cross-section is weld-affected (ksi). Use buckling constants for weld-affected zones and welded strengths.

A_{wz} = cross-sectional area of the weld-affected zone (in.²)

A_v = shear area defined in Articles 7.5.4.6.2, 7.5.4.6.3, and 7.5.4.6.4 (in.²)

7.5.4.6.2—Flat Elements Supported on Both Edges

C7.5.4.6.2

For the limit state of shear rupture:

This Article matches Section G.2 of the *Aluminum Design Manual* (AA, 2015).

- For unwelded members:

$$V_n = F_{su} A_n \quad (7.5.4.6.2-1)$$

- For welded members:

$$V_n = F_{su} (A_n - A_{wz}) + F_{suw} A_{wz} \quad (7.5.4.6.2-2)$$

where:

A_n = net area of the web (in.²)

F_{suw} = shear ultimate strength in the weld-affected zone (ksi)

A_{wz} = weld-affected area of the web (in.²)

For the limit states of shear yielding and shear buckling, V_n is as defined in Article 7.5.4.6.1 with $A_v = dt$ and F_{ns} determined from:

- If $b/t \leq \frac{B_s - F_{sy}}{1.25 D_s} = \lambda_1$, then

$$F_{ns} = F_{sy} \quad (7.5.4.6.2-3)$$

- If $\frac{B_s - F_{sy}}{1.25 D_s} < b/t < \frac{C_s}{1.25}$, then

$$F_{ns} = B_s - 1.25 D_s b/t \quad (7.5.4.6.2-4)$$

- If $b/t \geq \frac{C_s}{1.25}$, then

$$F_{ns} = \frac{\pi^2 E}{(1.25 b/t)^2} \quad (7.5.4.6.2-5)$$

For webs without transverse stiffeners, b shall be taken as the clear height of the web; for webs with transverse stiffeners, b shall be determined as:

$$b = \frac{a_1}{\sqrt{1 + 0.7 \left(\frac{a_1}{a_2} \right)^2}} \quad (7.5.4.6.2-6)$$

where:

a_1 = the lesser of the clear height of the web and the distance between stiffeners (in.)

a_2 = the greater of the clear height of the web and the distance between stiffeners (in.)

t = web thickness (in.)

A_w = area of the web (in.²) = dt

d = full depth of the section (in.)

B_s , D_s , and C_s = parameters specified in Table 7.5.4.3-1 or 7.5.4.3-2

Transverse stiffeners shall have a moment of inertia, I_s , not less than the following:

- If $\frac{s}{b} \leq 0.4$, then

$$I_s = \frac{0.55Vb^2}{E} \left(\frac{s}{b} \right) \quad (7.5.4.6.2-7)$$

- If $\frac{s}{b} > 0.4$, then

$$I_s = \frac{0.088Vb^2}{E} \left(\frac{b}{s} \right) \quad (7.5.4.6.2-8)$$

where:

- b = clear height of the web regardless of whether or not a longitudinal stiffener is present (in.)
- I_s = moment of inertia of the transverse stiffener (in.⁴). For a stiffener composed of members of equal size on each side of the web, the moment of inertia of the stiffener shall be computed about the centerline of the web. For a stiffener composed of a member on only one side of the web, the moment of inertia of the stiffener shall be computed about the face of the web in contact with the stiffener.
- s = distance between transverse stiffeners (in.). For a stiffener composed of a pair of members, one on each side of the web, the stiffener spacing, s , is the clear distance between the pairs of stiffeners. For a stiffener composed of a member on only one side of the web, the stiffener spacing, s , is the distance between fastener lines or other connecting lines.
- V = shear force on the web at the transverse stiffener (kip)

Transverse stiffeners shall consist of plates or angles welded or bolted to either one or both sides of the web. Stiffeners in straight girders not used as connection plates shall be tight fit or attached at the compression flange, but need not be in bearing with the tension flange.

7.5.4.6.3—Flat Elements Supported on One Edge

C7.5.4.6.3

For the limit state of shear rupture:

This Article matches Section G.3 of the *Aluminum Design Manual* (AA, 2015).

- For unwelded members:

$$V_n = F_{su} A_n \quad (7.5.4.6.3-1)$$
- For welded members:

$$V_n = F_{su} (A_n - A_{wz}) + F_{suw} A_{wz} \quad (7.5.4.6.3-2)$$

where:

- $$\begin{aligned} A_n &= \text{net area of the web} \\ A_{wz} &= \text{weld-affected area of the web} \end{aligned}$$

For the limit states of shear yielding and shear buckling, V_n is as defined in Article 7.5.4.6.1 with $A_v = bt$ and F_{ns} determined from the nominal shear resistance of flat elements supported on one edge shall be taken as:

- If $b/t \leq \frac{B_s - F_{sy}}{3.0D_s} = \lambda_1$, then

$$F_{ns} = F_{sy} \quad (7.5.4.6.3-3)$$

- If $\frac{B_s - F_{sy}}{3.0D_s} < b/t < \frac{C_s}{3.0}$, then

$$F_{ns} = B_s - 3.0D_s b/t \quad (7.5.4.6.3-4)$$

- If $b/t \geq \frac{C_s}{3.0}$, then

$$F_{ns} = \frac{\pi^2 E}{(3.0b/t)^2} \quad (7.5.4.6.3-5)$$

where:

b = distance from the unsupported edge to the mid-thickness of the supporting element (in.)

t = web thickness (in.)

A_w = area of the web (in.²) = bt

7.5.4.6.4—Pipes and Round or Oval Tubes

C7.5.4.6.4

For the limit state of shear rupture:

This Article matches Section G.4 of the *Aluminum Design Manual* (AA, 2015).

- For unwelded members:

$$V_n = F_{su} A_n / 2 \quad (7.5.4.6.4-1)$$

- For welded members:

$$V_n = F_{su} (A_n - A_{wz}) / 2 + F_{suw} A_{wz} / 2 \quad (7.5.4.6.4-2)$$

where:

A_n = net area of the pipe or tube (in.²)

A_{wz} = weld-affected area of the pipe or tube (in.²)

For the limit states of shear yielding and shear buckling, V_n is as defined in Article 7.5.4.6.1 with $A_v = \pi(D_o^2 - D_i^2)/8$, where D_o = outside diameter of the pipe or tube, D_i = inside diameter of the pipe or tube, and F_{ns} is determined as:

- If $\lambda_t \leq \frac{1.3B_s - F_{sy}}{1.63D_s} = \lambda_1$, then

$$F_{ns} = F_{sy} \quad (7.5.4.6.4-3)$$

- If $\frac{1.3B_s - F_{sy}}{1.63D_s} < \lambda_t < 1.25$, then

$$F_{ns} = 1.3B_s - 1.63D_s\lambda_f \quad (7.5.4.6.4-4)$$

- If $\lambda_t \geq \frac{C_s}{1.25}$, then

$$F_{ns} = \frac{1.3\pi^2 E}{(1.25\lambda_t)^2} \quad (7.5.4.6.4-5)$$

in which:

$$\lambda_t = 2.9 \left(\frac{R_b}{t} \right)^{5/8} \left(\frac{L_v}{R_b} \right)^{1/4} \quad (7.5.4.6.4-6)$$

where:

R_b = mid-thickness radius of a round tube or maximum mid-thickness radius of an oval tube (in.)

t = wall thickness of tube (in.)

L_v = length of tube from maximum to zero shear force (in.)

7.5.4.7—Elastic Buckling Stress of Elements

C7.5.4.7

The elastic buckling stress, F_e , of elements shall be determined using Table 7.5.4.7-1.

This Article matches Sections B.5.5.2 and B.5.6 of the *Aluminum Design Manual* (AA, 2015).

Table 7.5.4.7-1—Elastic Buckling Stress, F_e , of Elements

Element Type	Element Stress	Element Support	F_e (ksi)
Flat	Uniform Compression	Supported on both edges	$\frac{\pi^2 E}{(1.6b/t)^2}$
Flat	Uniform Compression	Supported on one edge	$\frac{\pi^2 E}{(5.0b/t)^2}$
Flat	Uniform Compression	Supported on one edge and with a stiffener on the other edge	$\left(1 - \rho_{ST}\right) \frac{\pi^2 E}{(5.0b/t)^2} + \rho_{ST} \frac{\pi^2 E}{(1.6b/t)^2}$
Flat	Uniform Compression	Supported on both edges and with an intermediate stiffener	$\frac{\pi^2 E}{\lambda_s^2}$
Curved	Uniform Compression	Supported on both edges	$\frac{\pi^2 E}{16 \left(\frac{R_b}{t}\right) \left(1 + \frac{\sqrt{R_b/t}}{35}\right)^2}$
Flat	Flexural Compression	Supported on one edge, compression edge free	$\frac{\pi^2 E}{(3.5b/t)^2}$

7.5.5—Extreme Event Limit State

All applicable extreme event load combinations in Table 3.4.1-1 shall be investigated. All resistance

factors for the extreme limit state shall be taken as 1.0.

Bolted joints not protected by capacity design or structural fuses may be assumed to behave as bearing-type connections at the extreme event limit state, and the resistance factors given in Article 7.5.4.2 shall apply.

7.6—FATIGUE

7.6.1—General

Fatigue shall be categorized as load- or distortion-induced fatigue.

7.6.2—Load-Induced Fatigue

7.6.2.1—Application

The force effect considered for the fatigue design of an aluminum bridge detail shall be the live load stress range. Residual stresses shall not be included in investigating fatigue.

These provisions shall be applied only to details subjected to a net applied tensile stress. In regions where the unfactored permanent loads produce compression, fatigue shall be considered only if the compressive stress is less than that resulting from the Fatigue I load combination specified in Table 3.4.1-1.

7.6.2.2—Design Criteria

For load-induced fatigue considerations, each detail shall satisfy:

$$\gamma(\Delta f) < (\Delta F)_n \quad (7.6.2.2-1)$$

where:

- γ = load factor specified in Table 3.4.1-1 for the fatigue load combination
- (Δf) = force effect, live load stress range due to the passage of the fatigue load as specified in Article 3.6.1.4 (ksi)
- $(\Delta F)_n$ = nominal fatigue resistance as specified in Article 7.6.2.5 (ksi)

7.6.2.3—Detail Categories

Components and details shall be designed to satisfy the requirements of their respective detail categories summarized in Table 7.6.2.3-1 and illustrated in Figure 7.6.2.3-1 which provides examples as guidelines and is not intended to exclude other similar details. Tensile stresses shall be considered to be positive and compressive stresses shall be considered to be negative.

C7.6.2.3

Table 7.6.2.3-1 matches Table 3.1 of the *Aluminum Design Manual* (AA, 2015).

The values in Table 7.6.2.3-2 were determined by equating infinite and finite life resistances with due regard to the difference in load factors used with the infinite (1.5 for Fatigue I) and finite life (0.75 for Fatigue II) load combinations. The values were computed using the values for C_f , m , and $(\Delta F)_{TH}$ given in Table 7.6.2.5-1

Bolt fabrication shall conform to the provisions of Article 11.4.8.5 of the *AASHTO LRFD Bridge Construction Specifications*. Where permitted for use, unless specific information is available to the contrary, bolt holes in cross-frame, diaphragm, and lateral bracing members and their connection plates shall be assumed for design to be punched full size.

Except as specified herein for fracture-critical members where the projected 75-year single lane Average Daily Truck Traffic ($ADTT_{SL}$) is less than or equal to that specified in Table 7.6.2.3-2 for the component or detail under consideration, that component or detail should be designed for finite life using the Fatigue II load combination specified in Table 3.4.1-1. Otherwise, the component or detail shall be designed for infinite life using the Fatigue I load combination. A single-lane Average Daily Truck Traffic ($ADTT_{SL}$) shall be computed as specified in Article 3.6.1.4.2.

and a number of stress range cycles per truck passage, n , equal to one, and rounded up to the nearest five trucks per day.

Table 7.6.2.3-1—Detail Categories for Load-Induced Fatigue

General Condition	Detail	Detail Category	Fatigue Design Details (Note 1)
Plain Material	Base metal with rolled, extruded, drawn, or cold finished surfaces; cut or sheared surfaces with ANSI/ASME B46.1 surface roughness $\leq 1,000 \mu\text{in.}$	A	1, 2
Built-up Members	Base metal and weld metal in members without attachments and built up of plates or shapes connected by continuous full- or partial-penetration groove welds or continuous fillet welds parallel to the direction of applied stress.	B	3, 4, 5
	Flexural stress in base metal at the toe of welds on girder webs or flanges adjacent to welded transverse stiffeners.	C	6, 21
	Base metal at the end of partial-length welded cover plates with square or tapered ends, with or without welds across the ends.	E	5
Mechanically Fastened Connections	Base metal at the gross section of slip-critical connections and at the net section of bearing connections, where the joint configuration does not result in out-of-plane bending in the connected material and the stress ratio (the ratio of minimum stress to maximum stress), R_S , is (Note 2):		
	$R_S \leq 0$	B	7
	$0 < R_S < 0.5$	D	7
	$R_S \geq 0.5$	E	7

(continued on next page)

Table 7.6.2.3-1 (continued)—Detail Categories for Load-Induced Fatigue

General Condition	Detail	Detail Category	Fatigue Design Details (Note 1)
Mechanically Fastened Connections (cont'd)	Base metal at the gross section of slip-critical connections and at the net section of bearing connections, where the joint configuration results in out-of-plane bending in connected material.	E	8
Fillet Welds	Base metal at intermittent fillet welds	E	
	Base metal at the junction of axially loaded members with fillet-welded end connections. Welds shall be disposed about the axis of the members so as to balance weld stresses.	E	15, 17
	Shear stress in weld metal of continuous or intermittent longitudinal or transverse fillet welds.	F	5, 15, 18
Groove Welds	Base metal and weld metal at full-penetration groove welded splices of parts of similar cross-section ground flush, with grinding in the direction of applied stress and with weld soundness established by radiographic or ultrasonic inspection.	B	9, 10
	Base metal and weld metal at full-penetration groove welded splices at transitions in width or thickness, with welds ground to slopes $\leq 1:2.5$, with grinding in the direction of applied stress, and with weld soundness established by radiographic or ultrasonic inspection.	B	11, 12
	Base metal and weld metal at full-penetration groove welded splices with or without transitions with slopes $\leq 1:2.5$, when reinforcement is not removed or weld soundness is not established by radiographic or ultrasonic inspection; or both.	C	9, 10, 11, 12
	Base metal and weld metal at full-penetration groove welds with permanent backing.	E	22
Attachments	Base metal detail of any length attached by groove welds subject to transverse or longitudinal loading, or both; with a transition radius $R \geq 2$ in., and with the weld termination ground smooth:		
	$R \geq 24$ in.	B	13
	$24 \text{ in.} > R \geq 6$ in.	C	13
	$6 \text{ in.} > R \geq 2$ in.	D	13
	Base metal at a detail attached by groove welds or fillet welds with a detail dimension parallel to the direction of stress $a < 2$ in.	C	19

(continued on next page)

Table 7.6.2.3-1 (continued)—Detail Categories for Load-Induced Fatigue

General Condition	Detail	Detail Category	Fatigue Design Details (Note 1)
Attachments (cont'd)	Base metal at a detail attached by groove welds or fillet welds with a detail dimension parallel to the direction of stress $a < 2$ in.	C	19
	Base metal at a detail attached by groove welds or fillet welds subject to longitudinal loading, with a transition radius, if any, < 2 in.:		
	$2 \text{ in.} \leq a \leq 12b$ or 4 in.	D	14
	Base metal at a detail attached by groove welds or fillet welds with a detail dimension parallel to the direction of stress $a < 2$ in.:	C	19
	$2 \text{ in.} \leq a \leq 12b$ or 4 in.	D	14
	$a > 12b$ or 4 in.	E	14, 19, 20
	Base metal at a detail of any length attached by fillet welds or partial-penetration groove welds in the direction parallel to the stress, with a transition radius $R \geq 2$ in., and the weld termination is ground smooth:		
	$R \geq 24$ in.	B	16
	$24 \text{ in.} > R > 6$ in.	C	16
	$6 \text{ in.} > R > 2$ in.	D	16

Notes:

1. See Figure 7.6.2.3-1. These examples are provided as guidelines and are not intended to exclude other similar details.
2. Tensile stresses are considered to be positive and compressive stresses are considered to be negative.

(continued on next page)

Figure 7.6.2.3-1—Illustrative Examples

Figure 7.6.2.3-1 (continued)—Illustrative Examples

Table 7.6.2.3-2—75-year $(ADTT)_{SL}$ Equivalent to Infinite Life

Detail Category	75-year $(ADTT)_{SL}$ Equivalent to Infinite Life (Trucks/Day)
A	20,410
B	5,085
C	2,310
D	2,465
E	2,115
F	2,005

7.6.2.4—Detailing to Reduce Constraint

To the extent practical, welded structures shall be detailed to avoid conditions that create highly constrained joints and crack-like geometric discontinuities that are susceptible to constraint-induced fracture. Welds that are parallel to the primary stress but interrupted by intersecting members shall be detailed to allow a minimum gap of 1.0 in. between weld toes.

7.6.2.5—Fatigue Resistance

Nominal fatigue resistance, $(\Delta F)_n$, shall be taken as:

- For the Fatigue I load combination and infinite life:
 $(\Delta F)_n = (\Delta F)_{TH}$ (7.6.2.5-1)
- For the Fatigue II load combination and finite life:
 $(\Delta F)_n = C_f / N^{1/m}$ (7.6.2.5-2)

in which:

$$N = (365)(75)n (ADTT)_{SL} \quad (7.6.2.5-3)$$

where:

- C_f = constant taken from Table 7.6.2.5-1 (ksi)
 m = constant taken from Table 7.6.2.5-1
 n = number of stress range cycles per truck taken from Table 6.6.1.2.5-1
 $(ADTT)_{SL}$ = single-lane ADTT as specified in Article 3.6.1.4
 $(\Delta F)_{TH}$ = constant amplitude threshold taken from Table 7.6.2.5-1

C7.6.2.5

Table 7.6.2.5-1 matches Table 3.2 of the *Aluminum Design Manual* and Eq. 7.6.2.5-2 matches the equation for fatigue strength given in Section 3.2 of the *Aluminum Design Manual* (AA, 2015). While the $S-N$ curves of different fatigue categories for steel are parallel, the curves for aluminum are not. When the curves were derived, the best fits were used. The $S-N$ curves for detail Classes C through F could be made parallel without significant loss of accuracy. However, this was not done in part to maintain some consistency with fatigue provisions developed in conjunction with European partners. From a fracture mechanics perspective, the relationship between incremental crack growth and applied stress intensity factor range is more complex than for steel, particularly in the slow growth regime, and is reflective of aluminum's microstructural barriers to crack growth extension, like sub-grain structures. Further, it seems clear that Class A details, like plain extruded sections, would be expected to have a different fatigue response than other classes with residual stresses caused by welds, and perhaps a significantly different $S-N$ curve slope.

Table 7.6.2.5-1—Detail Category Constant and Constant Amplitude Fatigue Threshold

Detail Category	C_f (ksi)	m	$(\Delta F)_{TH}$ (ksi)
A	96.5	6.85	10.2
B	130	4.84	5.4
C	278	3.64	4.0
D	157	3.73	2.5
E	160	3.45	1.8
F	174	3.42	1.9

7.6.3—Distortion-Induced Fatigue

Load paths that are sufficient to transmit all intended and unintended forces shall be provided by connecting all transverse members to appropriate components of the cross-section of longitudinal members. The load paths shall be provided by attaching the various components by either welding or bolting.

7.6.3.1—Transverse Connection Plates

The provisions of Article 6.6.1.3.1 shall apply.

7.6.3.2—Lateral Connection Plates

The provisions of Article 6.6.1.3.2 shall apply.

7.7—GENERAL DIMENSION AND DETAIL REQUIREMENTS**7.7.1—Effective Length of Span**

Span lengths shall be taken as the distance between centers of bearings or other points of support.

7.7.2—Dead Load Camber

Aluminum structures should be cambered during fabrication to compensate for dead load deflection and vertical alignment.

Deflection due to aluminum weight, steel weight, concrete weight, wearing surface weight, and loads not applied at the time of construction shall be reported separately.

Vertical camber shall be specified to account for the computed dead load deflection.

When staged construction is specified, the sequence of load application should be considered when determining the cambers.

7.7.3—Minimum Thickness

The nominal thickness of aluminum components shall not be less than 0.187 in.

C7.7.3

The minimum thickness of aluminum components depends primarily on resistance to damage during fabrication and handling rather than a need for corrosion allowance.

7.7.4—Diaphragms and Cross-Frames

Diaphragms and cross-frames shall conform to the intent of Articles 6.7.4.1, 6.7.4.2, 6.7.4.3, and 6.7.4.4, except the provisions for horizontally-curved girders.

7.7.5—Lateral Bracing

Lateral bracing shall conform to the intent of Article 6.7.5.

7.8—TENSION MEMBERS

7.8.1—General

Members and splices subjected to axial tension shall be investigated for:

- yield on the gross section, and
- fracture on the net section.

Holes larger than those typically used for connectors such as bolts shall be deducted in determining the gross section area, A_g .

The determination of the net section, A_n , requires consideration of:

- The gross area from which deductions will be made or reduction factors applied, as appropriate;
- Deductions for all holes in the design cross-section;
- Correction of the bolt hole deductions for the stagger rule specified in Article 7.8.3;
- Application of the reduction factor specified in Article 7.8.2.2 to account for shear lag.

Tension members shall satisfy the slenderness requirements specified in Article 7.8.4 and the fatigue requirements of Article 7.6. Block shear resistance shall be investigated at end connections as specified in Article 7.12.4.

7.8.2—Tensile Resistance

7.8.2.1—General

The factored tensile resistance, P_{rt} , shall be taken as the lesser of the values for tensile yielding on the gross section and tensile rupture on the net section.

- For tensile yielding on the gross section:

$$P_{rt} = \phi_y P_{ny} \quad (7.8.2.1-1)$$

in which:

- For unwelded members and members with transverse welds:

$$P_{ny} = F_y A_g \quad (7.8.2.1-2)$$

C7.8.2.1

This Article matches Section D.2 of the *Aluminum Design Manual* (AA, 2015).

- For members with longitudinal welds:

$$P_{ny} = F_{ty}(A_g - A_{wz}) + F_{tyw}A_{wz} \quad (7.8.2.1-3)$$

- For tensile rupture on the net section:

$$P_{rt} = \phi_u P_{mt} \quad (7.8.2.1-4)$$

in which:

- For unwelded members:

$$P_{nu} = F_{tu} A_e \quad (7.8.2.1-5)$$

- For welded members:

$$P_{nu} = F_{tu}(A_e - A_{wz}) + F_{tuw} A_{wz} \quad (7.8.2.1-6)$$

7.8.2.2—Effective Net Area

The effective net area, A_e , for angles, channels, tees, zees, and I-shaped sections shall be determined as follows:

- If tension is transmitted directly to each of the cross-sectional elements of the member by fasteners or welds, the effective net area, A_e , shall be taken as the net area, A_n .
- If tension is transmitted by fasteners or welds through some but not all of the cross-sectional elements of the member, the effective net area, A_e , shall be taken as:

$$A_e = UA_n \quad (7.8.2.2-1)$$

where:

A_n = net area of the member at the connection (in.²)
 U = reduction factor to account for shear lag taken as given in Article 6.8.2.1

The net effective area shall not be less than the net area of the connected elements.

7.8.2.3—Combined Tension and Flexure

A component subjected to tension and flexure shall satisfy Eq. 7.8.2.3-1.

$$\frac{P_{ul}}{P_{rl}} + \frac{M_{ux}}{M_{rx}} + \frac{M_{uy}}{M_{ry}} \leq 1.0 \quad (7.8.2.3-1)$$

where:

P_{nt} = axial tension resulting from the factored loads (kip)
 P_{rt} = factored tensile resistance (kip)

C7.8.2.2

This Article is similar to Section D.3.2 of the *Aluminum Design Manual* (AA, 2015), except for the reduction factor that accounts for shear lag.

C7.8.2.3

This Article matches Section H.1 of the *Aluminum Design Manual* (AA, 2015).

- M_{ux} = moment about the major principal axis resulting from the factored loads (kip-in.)
 M_{rx} = factored flexural resistance about the major principal axis (kip-in.)
 M_{uy} = moment about the minor principal axis resulting from the factored loads (kip-in.)
 M_{ry} = factored flexural resistance about the minor principal axis (kip-in.)

7.8.3—Net Area

The net area, A_n , of an element is the product of the thickness of the element and its smallest net width. The width of each drilled hole shall be taken as the nominal diameter of the hole and the width of each punched hole shall be taken as the nominal diameter of the hole plus 0.0313 in. The net width shall be determined for each chain of holes extending across the member or along any transverse, diagonal, or zigzag line.

The net width for each chain shall be determined by subtracting from the width of the element the sum of the widths of all holes in the chain and adding the quantity $s^2/4g$ for each space between consecutive holes in the chain.

where:

- s = longitudinal center-to-center distance (pitch) between two holes (in.)
 g = transverse center-to-center distance (gauge) between two holes (in.)

7.8.4—Limiting Slenderness Ratio

Tension members other than rods, eyebars, and plates shall satisfy the slenderness requirements specified below:

- For primary members subject to stress reversals, $l/r \leq 140$
- For primary members not subject to stress reversals, $l/r \leq 200$
- For secondary members, $l/r \leq 240$

where:

- l = unbraced length (in.)
 r = radius of gyration (in.)

7.8.5—Built-Up Members

The main elements of built-up tension members shall be connected by continuous plates with or without perforations, or by tie plates with or without lacing. Welded connections between shapes and plates shall be continuous. Bolted connections between shapes and plates shall conform to Articles 7.12.2 and 7.12.5.

7.9—COMPRESSION MEMBERS

7.9.1—General

The provisions of this Article shall apply to prismatic aluminum members subjected to either axial compression, or combined axial compression and flexure.

7.9.2—Axial Compression Resistance

The factored resistance, P_{rc} , of components in axial compression shall be taken as:

$$P_{rc} = \phi_c P_n \quad (7.9.2-1)$$

where:

P_n = least of the nominal compressive resistance for member buckling specified in Article 7.9.2.1, the nominal compressive resistance for local buckling specified in Article 7.9.2.2, and the nominal compressive resistance for the interaction between member buckling and local buckling specified in Article 7.9.2.3 (kip)

ϕ_c = resistance factor for compression specified in Article 7.5.4.2

7.9.2.1—Member Buckling

7.9.2.1.1—General

The nominal compressive resistance, P_n , for member buckling is:

$$P_n = F_c A_g \quad (7.9.2.1.1-1)$$

in which the compressive buckling stress, F_c , shall be taken as:

- If $\frac{Kl}{r} \leq \lambda_1$, then $F_c = F_{cr}$ (7.9.2.1.1-2)

- If $\lambda_1 < \frac{Kl}{r} < C_c$, then

$$F_c = (B_c - D_c \lambda) \left(0.85 + 0.15 \frac{C_c - \lambda}{C_c - \lambda_1} \right) \quad (7.9.2.1.1-3)$$

- If $\frac{KI}{r} \geq C_c$, then

$$F_c = \frac{0.85\pi^2 E}{\left(\frac{KI}{r}\right)^2} \quad (7.9.2.1.1-4)$$

C7.9.2

The Article matches Section E.1 of the *Aluminum Design Manual* (AA, 2015).

C7.9.2.1.1

This Article matches Section E.2 of the *Aluminum Design Manual* (AA, 2015).

$$\lambda_1 = \frac{B_c - F_{cy}}{D_c} \quad (7.9.2.1.1-5)$$

where:

Kl/r = largest column effective slenderness determined from Articles 7.9.2.1.2 and 7.9.2.1.3
 λ = axial slenderness ratio, Kl/r
 B_c , D_c , and C_c = parameters specified in Table 7.5.4.3-1 or 7.5.4.3-2

The effective length factor, K , shall be determined in accordance with Article 4.6.2.5. For members without welds, B_c , D_c , C_c , and F_{cy} shall be determined using unwelded material properties. For members whose cross-section is fully weld-affected over the entire length of the member, B_c , D_c , C_c , and F_{cy} shall be determined using welded material properties. For other members:

- For members supported at both ends and with no transverse weld farther than $0.05L$ from the member ends, B_c , D_c , C_c , and F_{cy} shall be determined using unwelded material properties.
- For members supported at both ends with a transverse weld farther than $0.05L$ from the member ends and for members supported at only one end with a transverse weld, B_c , D_c , C_c , and F_{cy} shall be determined using welded material properties.
- For members with longitudinal welds:

The nominal member buckling resistance, P_n , is

$$P_n = P_{no} \left(1 - \frac{A_{wz}}{A_g} \right) + P_{nw} \left(\frac{A_{wz}}{A_g} \right) \quad (7.9.2.1.1-6)$$

where:

P_{no} = nominal member buckling resistance if no part of the cross-section is weld-affected (kip)
 P_{nw} = nominal member buckling resistance if the entire cross-section is weld-affected (kip)

7.9.2.1.2—Flexural Buckling

C7.9.2.1.2

For flexural buckling, Kl/r is the largest slenderness ratio of the column.

This Article matches Section E.2.1 of the *Aluminum Design Manual* (AA, 2015).

7.9.2.1.3—Torsional and Flexural–Torsional Buckling

C7.9.2.1.3

For torsional or flexural–torsional buckling, Kl/r shall be taken as the larger of the slenderness ratio for flexural buckling and the equivalent slenderness ratio, which shall be determined as:

This Article matches Section E.2.2 of the *Aluminum Design Manual* (AA, 2015).

- I_x, I_y = moments of inertia about the principal axes (in.⁴)
 r_x, r_y = radii of gyration about the centroidal principal axes (in.)

7.9.2.2—Local Buckling

7.9.2.2.1—General

For members without welds, the nominal compressive resistance, P_n , for local buckling shall be determined in accordance with either Article 7.9.2.2.2 or 7.9.2.2.3. For members with welds, the local buckling resistance shall be determined in accordance with Article 7.9.2.2.2.

C7.9.2.2.1

This Article matches Section E.3 of the *Aluminum Design Manual* (AA, 2015).

7.9.2.2.2—Weighted Average Local Buckling Resistance

C7.9.2.2.2

The weighted average local buckling resistance may be determined as:

This Article matches Section E.3.1 of the *Aluminum Design Manual* (AA, 2015).

$$P_n = \sum_{i=1}^n F_{nci} A_i + F_{cv} \left(A_g - \sum_{i=1}^n A_i \right) \quad (7.9.2.2.2-1)$$

where:

- F_{nci} = nominal local buckling resistance of element i computed per Articles 7.5.4.4.1 through 7.5.4.4.6 (ksi)
 A_i = area of element i (in.²)

7.9.2.2.3—Alternative Local Buckling Resistance

C7.9.2.2.3

As an alternative to Article 7.9.2.2.2, the local buckling resistance of a shape composed of flat elements may be determined as:

This Article matches Section E.3.2 of the *Aluminum Design Manual* (AA, 2015). Article 7.9.2.2.3 may be used for shapes not addressed by Article 7.5.4.4, or for a more accurate determination of local buckling resistance of any shape.

$$P_n = F_{nc} A_g \quad (7.9.2.2.3-1)$$

where F_{nc} is determined in accordance with Article 7.5.4.4.7.

7.9.2.3—Interaction between Member Buckling and Local Buckling

C7.9.2.3

If the elastic local buckling stress, F_e , is less than the member buckling stress given by Eq. 7.9.2.1.1-2 or 7.9.2.1.1-3 as appropriate, the nominal compressive resistance of the member shall not exceed:

This Article matches Section E.4 of the *Aluminum Design Manual* (AA, 2015).

$$P_n = \left[\frac{0.85\pi^2 E}{(KL/r)^2} \right]^{1/3} F_e^{2/3} A_g \quad (7.9.2.3-1)$$

If the local buckling resistance is determined from Article 7.9.2.2.2, F_e is the smallest elastic local buckling

7.10—FLEXURAL MEMBERS**C7.10**

This Article matches Chapter F of the *Aluminum Design Manual* (AA, 2015).

7.10.1—General

This Article addresses members subjected to flexure that are either:

- loaded in a plane parallel to a principal axis that passes through the shear center, or
- restrained against rotation about their longitudinal axis at load points and supports.

The factored flexural resistance, M_r , shall be taken as:

$$M_r = \phi M_n \quad (7.10.1-1)$$

where:

ϕ = resistance factor for flexure specified in Article 7.5.4.2, taken as:

- ϕ_{ft} for flexural tensile rupture, or
- ϕ_f for all other flexural limit states

M_r shall be taken as the factored flexural resistance (kip-in.) which is the least of the factored flexural resistances for yielding and rupture specified in Article 7.10.2, local buckling specified in Article 7.10.3, and lateral-torsional buckling specified in Article 7.10.4.

7.10.2—Yielding and Rupture

For the limit state of yielding, the flexural resistance, M_{np} , is the least of Z , F_{cy} , $1.5S_tF_{ty}$, and $1.5S_cF_{cy}$.

For the limit state of rupture, the flexural resistance is:

$$M_{nu} = \frac{ZF_{tu}}{k_f} \quad (7.10.2-1)$$

where:

- Z = plastic modulus (in.³)
- S_t = section modulus on the tension side of the neutral axis (in.³)
- S_c = section modulus on the compression side of the neutral axis (in.³)

7.10.3.2—Direct Strength Method

$$M_{nlb} = F_b S_{xc} \quad (7.10.3.2-1)$$

where F_b is determined in accordance with Article 7.5.4.5.6.

7.10.3.3—Limiting Element Method

The flexural resistance for local buckling, M_{nlb} , is determined by limiting the stress in any element to the local buckling stress of that element, determined in accordance with Articles 7.5.4.4.2 through 7.5.4.4.6 and 7.5.4.5.2 through 7.5.4.5.5.

7.10.4—Lateral-Torsional Buckling

For the limit state of lateral-torsional buckling, the flexural resistance is M_{nmb} where:

Limit State	M_{nmb}	Slenderness Limits
Inelastic Buckling	$M_{np} \left(1 - \frac{\lambda}{C_c} \right) + \frac{\pi^2 E \lambda S_{xc}}{C_c^3}$	$\lambda \leq C_c$
Elastic Buckling	$\frac{\pi^2 E S_{xc}}{\lambda^2}$	$\lambda > C_c$

for lateral-torsional buckling about an axis designated as the x-axis.

To determine the lateral-torsional buckling slenderness, λ , use Articles 7.10.4.2.1 through 7.10.4.2.5. If more than one Article applies, any applicable Article shall be used.

For members without welds, determine the lateral-torsional buckling resistance, $M_{nmb} = M_{nmbos}$, using C_c for unwelded material using Table 7.5.4.3-1 or Table 7.5.4.3-2 and F_{cy} .

For members that are fully weld-affected, determine the lateral-torsional buckling resistance, $M_{nmb} = M_{nmbw}$, using C_c for welded material using Table 7.5.4.3-1 and F_{cyw} .

For members with transverse welds and:

- supported at both ends with no transverse weld farther than $0.05L$ from the member ends, $M_{nmb} = M_{nmbos}$
- supported at both ends with a transverse weld farther than $0.05L$ from the member ends, or supported at only one end with a transverse weld, $M_{nmb} = M_{nmbw}$

For members with longitudinal welds, the lateral-torsional buckling resistance, M_{nmb} , is:

7.10.4.1.2—Singly Symmetric Shapes

For singly symmetric shapes between brace points:

- If $I_{yc}/I_y < 0.1$ or $I_{yc}/I_y > 0.9$, $C_b = 1.0$
- If $0.1 < I_{yc}/I_y < 0.9$, C_b shall be determined using Article 7.10.4.1.1

If M_{max} produces compression on the larger flange and the smaller flange is also subjected to compression in the unbraced length, the member shall be checked at the location of M_{max} using C_b determined using Article 7.10.4.1.1, and at the location where the smaller flange is subjected to its maximum compression using $C_b = 1.67$.

7.10.4.2—Slenderness for Lateral–Torsional Buckling

7.10.4.2.1—Shapes Symmetric about the Bending Axis

The slenderness for shapes symmetric about the bending axis is:

$$\lambda = \frac{L_b}{r_{ye}\sqrt{C_b}} \quad (7.10.4.2.1-1)$$

where:

L_b = unbraced length (in.)

r_{ye} is:

- Between brace points of beams subjected to end moment only or to transverse loads applied at the beam's neutral axis, or at brace points:

$$r_{ye} = \sqrt{\frac{\sqrt{I_y}}{S_x} \sqrt{C_w + 0.038JL_b^2}} \quad (7.10.4.2.1-2)$$

- Between brace points of beams subjected to transverse loads applied on the top or bottom fiber (where the load is free to move laterally with the beam if the beam buckles):

$$r_{ye} = \sqrt{\frac{I_y}{S_x} \left[\pm \frac{d}{4} + \sqrt{\frac{d^2}{16} + \frac{C_w}{I_y} + \frac{0.038JL_b^2}{I_y}} \right]} \quad (7.10.4.2.1-3)$$

$d/4$ is negative when the load acts toward the shear center and positive when the load acts away from the shear center.

where:

where:

The y -axis is the centroidal symmetry or principal axis such that the tension flange has a positive y coordinate and bending is about the x -axis. The origin of the coordinate system is the intersection of the principal axes.

$$U = C_1 g_0 - \frac{C_2 \beta_x}{2} \quad (7.10.4.2.5-3)$$

C_1 and C_2 :

- If no transverse loads are applied between the ends of the unbraced segment, $C_1 = 0$ and $C_2 = 1$.
- If transverse loads are applied between the ends of the unbraced segment, C_1 and C_2 shall be taken as 0.5 or determined by rational analysis.

g_0 = distance from the shear center to the point of application of the load; g_0 is positive when the load acts away from the shear center and negative when the load acts towards the shear center. If there is no transverse load (pure moment cases), $g_0 = 0$.

$$\beta_x = \frac{1}{I_x} \left(\int_A y^3 dA + \int_A yx^2 dA \right) - 2y_0 \quad (7.10.4.2.5-4)$$

For singly symmetric I-shapes, as an alternative,

$$\beta_x = 0.9d_f \left(\frac{2I_{yc}}{I_y} - 1 \right) \left[1 - \left(\frac{I_y}{I_x} \right)^2 \right] \quad (7.10.4.2.5-5)$$

where:

d_f = the distance between the flange centroids; for tees, d_f is the distance between the flange centroid and the tip of the stem (in.)

I_{yc} = moment of inertia of the compression flange about the y -axis (in.³)

Alternately, for singly symmetric I-shapes where the smaller flange area is not less than 80 percent of the larger flange area, β_x shall be taken as $-2y_0$.

y_0 = the shear center's y -coordinate (in.)

7.10.4.3—Interaction between Local Buckling and Lateral–Torsional Buckling

For open shapes:

- whose flanges are flat elements in uniform compression supported on one edge and

$$R_n = \frac{C_{wa}(N + 5.4)}{C_{wb}} \quad (7.11.2.1-2)$$

- For concentrated forces applied at a distance from a member support that is less than $d/2$:

$$R_n = \frac{1.2C_{wa}(N + 1.3)}{C_{wb}} \quad (7.11.2.1-3)$$

in which:

$$C_{wa} = t^2 \sin \theta_w \left(0.46F_{cy} + 0.02\sqrt{EF_{cy}} \right) \quad (7.11.2.1-4)$$

$$C_{wb} = 0.4 + R_i(1 - \cos \theta_w) \quad (7.11.2.1-5)$$

where:

- d = member depth (in.)
- N = length of the bearing surface at the concentrated force (in.)
- t = web thickness (in.)
- θ_w = angle between the plane of web and the plane of the bearing surface ($\theta_w \leq 90^\circ$)
- R_i = for extruded shapes, $R_i = 0$; for all other shapes, R_i is the inside bend radius at the juncture of the flange and web (in.)

7.11.2.2—Bearing Stiffeners

Bearing stiffeners at concentrated forces shall be sufficiently connected to the web to transmit the concentrated force. Such stiffeners shall form a tight and uniform bearing against the flanges unless welds designed to transmit the full concentrated force are provided between flange and stiffener. Only the part of a stiffener cross-section outside the flange-to-web fillet shall be considered effective in bearing. The bearing stiffener shall meet the requirements of Article 7.9 with the length of the stiffener equal to the height of the web.

7.11.2.3—Combined Crippling and Bending of Flat Webs

Combinations of bending and concentrated forces applied at a distance of one-half or more of the member depth from the member support shall satisfy the following equation:

$$\left(\frac{R_u}{R_r} \right)^{1.5} + \left(\frac{M_u}{M_r} \right)^{1.5} \leq 1.0 \quad (7.11.2.3-1)$$

C7.11.2.2

This Article matches Section J.9.2 of the *Aluminum Design Manual* (AA, 2015).

C7.11.2.3

This Article matches Section J.9.3 of the *Aluminum Design Manual* (AA, 2015).

where:

- R_u = concentrated force resulting from factored loads (kip)
 R_r = factored concentrated force resistance determined in accordance with Article 7.11.2.1 (kip)
 M_u = moment in the member at the location of the concentrated force resulting from factored loads (kip-in.)
 M_r = factored flexural resistance determined in accordance with Article 7.10 (kip-in.)

7.12—CONNECTIONS AND SPLICES

7.12.1—General

Connections shall be designed for the factored member force effects.

Members and connections shall be designed for the effects of any eccentricity in joints.

7.12.2—Bolted Connections

7.12.2.1—General

Bolted connections, except for lacing and handrails, shall not contain less than two bolts.

Contract documents shall specify that all joint surfaces, including surfaces under bolt heads, nuts, and washers, shall be free from foreign material.

Articles 6.13.2.1.1 and 6.13.2.1.2 shall be used to determine whether a connection shall be designed as a slip-critical connection or a bearing connection. Only A325 bolts shall be used in slip-critical connections. The slip resistance of slip-critical connections shall be determined in accordance with Article 7.12.2.8.

7.12.2.2—Factored Resistance

For slip-critical connections, the factored resistance, R_r , of a bolt at the Service II Load Combination shall be taken as:

$$R_r = R_n \quad (7.12.2.2-1)$$

where:

R_n = nominal slip resistance specified in Article 7.12.2.8

The factored resistance, R_r or T_r , of a bolted connection at the strength limit state shall be taken as either:

$$R_r = \phi R_n \quad (7.12.2.2-2)$$

C7.12.2.1

Additional requirements related to bolts, nuts, and washers are provided in Article 7.4.3.

C7.12.2.2

This Article is similar to Article 6.13.2.2.

The resistance of steel parts of the connection (the bolts) is addressed in Section 6, and the resistance of the aluminum parts of the connection (the connected parts) is addressed in Section 7.

or:

$$T_r = \phi T_n \quad (7.12.2.2-3)$$

where:

ϕ = resistance factor for bolts taken as"

- ϕ_s for bolts in shear as specified in Article 6.5.4.2
- ϕ_t for bolts in tension as specified in Article 6.5.4.2
- ϕ_{bb} for bolts in bearing as specified in Article 7.5.4.2
- ϕ_y or ϕ_u for connected material in tension as specified in Article 7.5.4.2
- ϕ_v for connected material in shear as specified in Article 7.5.4.2

R_n = nominal shear resistance of the bolt or connected material taken as follows:

- For bolts in shear, R_n shall be taken as specified in Article 7.12.2.7
- For the connected material, R_n shall be taken as specified in Article 7.12.2.9
- For the connected material in tension or shear, R_n shall be taken as specified in Article 7.12.5

T_n = nominal tensile resistance of the bolt taken as follows:

- For bolts in tension, T_n shall be taken as specified in Article 7.12.2.10
- For bolts in combined tension and shear, T_n shall be taken as specified in Article 7.12.2.11

7.12.2.3—Washers

Hardened washers shall be provided for A325 bolted connections where required by Article 6.13.2.3.2.

7.12.2.4—Holes

Holes shall comply with Article 6.13.2.4.

7.12.2.5—Size of Bolts

The size of bolts shall comply with Article 6.13.2.5, except that the minimum nominal diameter shall be 0.5 in.

7.12.2.6—Spacing of Bolts

7.12.2.6.1—Minimum Spacing and Clear Distance

The distance between bolt centers shall not be less than 2.5 times the nominal diameter of the bolt. For

C7.12.2.6.1

The requirement for the distance between hole centers matches Section J.3.2 of the *Aluminum Design*

oversized or slotted holes, the minimum clear distance between the edges of adjacent bolt holes shall not be less than twice the nominal diameter of the bolt.

7.12.2.6.2—Minimum Edge Distance

The distance from the center of a bolt to an edge of a part shall not be less than 1.5 times the nominal diameter of the bolt. See Article 7.12.2.9 for the effect of edge distance on bearing strength.

7.12.2.7—Shear Resistance

The nominal shear resistance of bolts shall be determined in accordance with Article 6.13.2.7.

7.12.2.8—Slip Resistance

The nominal slip resistance of a bolt in a slip-critical connection shall be determined in accordance with Article 6.13.2.8. Aluminum members in slip-critical connections shall have tensile yield strength of at least 15 ksi. Aluminum surfaces abrasion-blasted with coal slag to SSPC SP-5 (SSPC, 2007) to an average substrate profile of 2.0 mils in contact with similar aluminum surfaces or zinc painted steel surfaces with a maximum dry film thickness of 4 mils shall be considered to be Class B surface conditions. Slip coefficients for other surfaces shall be determined in accordance with the Research Council on Structural Connection's *Specification for Structural Joints Using High Strength Bolts* (RCSC, 2009).

7.12.2.9—Bearing Resistance at Holes and Slots

The nominal bearing resistance of a connected part shall be determined as follows:

- For a bolt in a hole:

$$R_n = d_e t F_{tu} \leq 2 D t F_{tu} \quad (7.12.2.9-1)$$

- For a bolt in a slot with the slot perpendicular to the direction of force:

$$R_n = 1.33 D t F_{tu} \quad (7.12.2.9-2)$$

The edge distance perpendicular to the slot length and slot length shall be sized to avoid overstressing the material between the slot and the edge of the part. where:

- d_e = distance from the center of the bolt to the edge of the part in the direction of force (in.)
- t = for plain holes, thickness of the connected part;
for countersunk holes, thickness of the

Manual (AA, 2015). The requirement for the clear distance between the edges of adjacent holes matches Article 6.13.2.6.1.

C7.12.2.6.2

This Article matches Section J.3.3 of the *Aluminum Design Manual* (AA, 2015). Bearing strength is reduced when the hole is less than two bolt diameters from an edge.

C7.12.2.8

This Article matches Section J.3.7 of the *Aluminum Design Manual* (AA, 2015).

C7.12.2.9

This Article matches Section J.3.6 of the *Aluminum Design Manual* (AA, 2015).

connected part less $\frac{1}{2}$ the countersink depth (in.)
 F_{tu} = tensile ultimate strength of the connected part (ksi)
 D = nominal diameter of the bolt (in.)

7.12.2.10—Tensile Resistance

The nominal tensile resistance of bolts shall be determined as specified in Article 6.13.2.10.

7.12.2.11—Combined Tension and Shear

The nominal tensile resistance of bolts subjected to combined shear and axial tension shall be determined in accordance with Article 6.13.2.11.

7.12.2.12—Shear Resistance of Anchor Bolts

The nominal shear resistance of anchor bolts shall be determined in accordance with Article 6.13.2.12.

7.12.3—Welded Connections

7.12.3.1—General

Welding shall comply with AWS D1.2/D1.2M.

7.12.3.2—Factored Resistance

7.12.3.2.1—General

The factored resistance of welded connections, R_r , at the strength limit state shall be taken as given in Articles 7.12.3.2.2 through 7.12.3.2.4. Filler strengths shall be taken from Table 7.12.3.2.1-1.

C7.12.3.2.1

Filler strengths given in Table 7.12.3.2.1-1 match those in Table A.3.6 in the *Aluminum Design Manual* (AA, 2015).

Table 7.12.3.2.1-1—Filler Strengths

Filler	Tensile Ultimate Strength, F_{tew} (ksi)
4043	24
5183	40
5356	35
5556	42

7.12.3.2.2—Complete Penetration Groove-Welded Connections

7.12.3.2.2a—Tension and Compression

The factored resistance of complete penetration groove-welded connections subjected to tension or compression normal to the effective area of the weld shall be taken as:

$$R_r = \phi_e F_{tew} \quad (7.12.3.2.2a-1)$$

C7.12.3.2.2a

The strength of complete penetration groove welds may be governed by the welded strength of either of the base metals joined or by the strength of the filler metal. Usually, the filler metal is selected so that its strength equals or exceeds the strength of the welded base metals, but this is not required.

F_{tuw} = tensile ultimate strength of the filler (ksi) from Table 7.12.3.2.1-1

or:

$$R_r = \phi_e F_{tuw} \quad (7.12.3.2.3a-2)$$

where:

ϕ_e = resistance factor for base metal at welds specified in Article 7.5.4.2

F_{tuw} = welded tensile ultimate strength of the base metal from Article 7.4.1 (ksi)

The factored resistance of partial penetration groove-welded connections subjected to tension or compression parallel to the axis of the weld or compression normal to the effective area shall be taken as the factored resistance of the base metal.

7.12.3.2.3b—Shear

The factored resistance of partial penetration groove-welded connections subjected to shear on the effective area of the weld shall be taken as the lesser of:

$$R_r = 0.6\phi_e F_{suw} \quad (7.12.3.2.3b-1)$$

where:

ϕ_e = resistance factor for weld metal specified in Article 7.5.4.2

F_{suw} = shear ultimate strength of the filler taken as $0.5F_{tuw}$, where F_{tuw} is determined from Table 7.12.3.2.1-1 (ksi)

or:

$$R_r = \phi_e F_{suw} \quad (7.12.3.2.3b-2)$$

where:

ϕ_e = resistance factor for base metal at welds specified in Article 7.5.4.2

F_{suw} = welded shear ultimate strength of the base metal from Article 7.4.1 (ksi)

7.12.3.2.4—Fillet-Welded Connections

The factored resistance of fillet-welded connections subjected to tension or compression parallel to the axis of the weld or compression normal to the axis of the weld shall be taken as the factored resistance of the base metal.

C7.12.3.2.4

The strength of fillet welds may be governed by either the base metal's welded strength or by the filler metal strength. Usually (but not always), the strength of the filler metal governs the strength of the joint because the area of the weld is based on the weld throat, which is

The factored resistance of fillet-welded connections subjected to tension perpendicular to the axis of the weld or shear shall be taken as:

$$R_r = \phi_e F_{sw} \quad (7.12.3.2.4-1)$$

where:

ϕ_e = resistance factor for weld metal specified in Article 7.5.4.2

F_{sw} = least of (kips/in.):

- the product of the weld filler's shear ultimate strength, $0.5F_{tww}$ (ksi), and the weld's effective throat (in.)
- for base metal in shear at the weld-base metal joint, the product of the base metal's welded shear ultimate strength, $0.6F_{tww}$ (ksi), and the fillet size, S_w (in.)
- for base metal in tension at the weld-base metal joint, the product of the base metal's welded tensile ultimate strength, F_{tww} (ksi), and the fillet size, S_w (in.)

Welded tensile ultimate strengths of base metals shall be determined from Article 7.4.1 and tensile ultimate strengths of weld fillers from Table 7.12.3.2.1-1.

7.12.3.3—Effective Area

The effective area shall be determined as defined in AWS D1.2/D1.2M.

7.12.3.4—Size of Fillet Welds

The size used in design of a fillet weld along edges of connected parts shall not exceed:

- For material less than 0.25 in. thick, the thickness of the material;
- For material 0.25 in. or more in thickness, 0.625 in. less than the material thickness, unless the weld is designated on the contract documents to be built out to obtain full throat thickness.

The minimum size of a fillet weld shall be as given in Table 7.12.3.4-1, except that the weld size shall not exceed the thickness of the thinner part joined.

less than the area of the base metal which is based on the weld size.

C7.12.3.3

Weld effective areas given in the *Aluminum Design Manual* (AA, 2015) match those given in AWS D1.2/D1.2M.

C7.12.3.4

Maximum fillet weld size requirements match those given in Article 6.13.3.4 for steel welds. Minimum fillet weld size requirements match those given in AWS D1.2/D1.2M, Table 2.2. If fillet welds are too small they may crack upon cooling or when stressed by unanticipated loads.

Base Metal Thickness, t , of Thicker Part Joined (in.)	Minimum Size of Fillet Weld (in.)
$t \leq 0.25$	0.125
$0.25 < t \leq 0.5$	0.1875
$t > 0.5$	0.25

Fillet weld end returns shall comply with Article 6.13.3.6.

C7.12.4

This Article matches Section J.7.3 of the *Aluminum Design Manual* (AA, 2015).

where:

For connections on a failure path with shear on some segments and tension on the other segments:

$$R_n = F_{sv} A_{gv} + F_{tu} A_{nt} \quad (7.12.4-2)$$

otherwise:

where for bolted connections:

$$A_{nt} = \text{net area in tension (in.}^2\text{)}$$
$$A_{nv} = \text{net area in shear (in.}^2\text{)}$$
$$A_{gv} = \text{gross area in shear (in.}^2\text{)}$$
$$F_{ty} = \text{specified minimum tensile yield strength (ksi)}$$
$$A_{gt} = \text{gross area in tension (in.}^2\text{)}$$

For weld-affected zones, use F_{nw} for F_m and F_{suw} for F_{su} .

7.12.5—Connection Elements**7.12.5.1—General**

This Article applies to the design of connection elements such as plates, gussets, angles, and brackets.

7.12.5.2—Tension

The factored tensile resistance, R_t , of connection elements is the lesser of the resistances for tensile yielding and tensile rupture given in Article 7.8.2.1.

7.12.5.3—Shear

The factored shear resistance, R_r , of connection elements is the lesser of the resistances for shear yielding and shear rupture. The factored shear yielding resistance of connection elements shall be taken as:

$$R_r = \phi_v F_{sy} A_{gv} \quad (7.12.5.3-1)$$

where:

- ϕ_v = resistance factor for shear specified in Article 7.5.4.2
- F_{sy} = shear yield strength of the connection element (ksi)
- A_{gv} = gross area of the connection element subject to shear (in.²)

The factored shear rupture resistance of connection elements shall be taken as:

$$R_r = \phi_{vu} F_{su} A_{nv} \quad (7.12.5.3-2)$$

where:

- ϕ_{vu} = resistance factor for shear rupture of connection elements specified in Article 7.5.4.2
- F_{su} = shear ultimate strength of the connection element (ksi)
- A_{nv} = net area of the connection element subject to shear (in.²)

For welded connection elements, $F_{sy} = F_{syw}$ and $F_{su} = F_{suw}$.

where:

- F_{syw} = shear yield strength in the weld-affected zone (ksi)

7.12.6—Splices

Splices shall be designed at the strength limit state to satisfy the connection requirements of Article 7.12.1.

C7.12.5.3

This Article is similar to Article 6.13.5.3.

7.12.7—Pins**7.12.7.1—Factored Resistance**

The factored resistance of a pinned connection shall be taken as:

$$R_r = \phi R_n \quad (7.12.7.1-1)$$

or

$$M_r = \phi M_n \quad (7.12.7.1-2)$$

where:

ϕ = resistance factor for pins taken as:

- ϕ_v for yielding of pins in shear as specified in Article 7.5.4.2
- ϕ_{vu} for rupture of pins in shear as specified in Article 7.5.4.2
- ϕ_f for yielding of pins in flexure as specified in Article 7.5.4.2
- ϕ_{fn} for rupture of pins in flexure as specified in Article 7.5.4.2
- ϕ_b for pins in bearing as specified in Article 7.5.4.2
- ϕ_{vu} for connected material in shear as specified in Article 7.5.4.2

R_n = nominal shear resistance of the pin or connected material taken as follows:

- For yielding of pins in shear, R_n shall be taken as specified in Article 7.12.7.4
- For rupture of pins in shear, R_n shall be taken as specified in Article 7.12.7.4
- For pins in bearing, R_n shall be taken as specified in Article 7.12.7.6
- For the connected material in shear, R_n shall be taken as specified in Article 7.12.5.3

M_n = nominal flexural resistance of the pin taken as follows:

- For yielding of pins in flexure, R_n shall be taken as specified in Article 7.12.7.5
- For rupture of pins in flexure, R_n shall be taken as specified in Article 7.12.7.5

7.12.7.2—Minimum Edge Distance

The distance from the center of a pin to the edge of a part shall not be less than 1.5 times the nominal diameter of the pin. See Article 7.12.7.6 for the effect of edge distance on bearing strength.

C7.12.7.1

This Article matches Section J.6 of the *Aluminum Design Manual* (AA, 2015).

7.12.7.3—Holes

The nominal diameter of holes for pins shall not be more than 0.0313 in. greater than the nominal diameter of the pin.

7.12.7.4—Shear Resistance

The nominal resistance for shear yielding is:

$$R_n = \frac{\pi D^2 F_{sy}}{4} \quad (7.12.7.4-1)$$

where:

D = nominal diameter of the pin (in.)
 F_{sy} = shear yield strength of the pin determined in accordance with Table 7.4.1-3

The nominal resistance for shear rupture is:

$$R_n = \frac{\pi D^2 F_{su}}{4} \quad (7.12.7.4-2)$$

where:

D = nominal diameter of the pin (in.)
 F_{su} = shear ultimate strength of the pin determined in accordance with Table 7.4.1-3

7.12.7.5—Flexural Resistance

The nominal resistance for flexural yielding is:

$$M_n = \frac{\pi D^3 F_{ty}}{21.3} \quad (7.12.7.5-1)$$

where:

D = nominal diameter of the pin (in.)
 F_{ty} = tensile yield strength of the pin determined in accordance with Table 7.4.1-1

The nominal resistance for flexural rupture is:

$$M_n = \frac{\pi D^3 F_{tu}}{21.3} \quad (7.12.7.5-2)$$

where:

D = nominal diameter of the pin (in.)
 F_{tu} = tensile ultimate strength of the pin determined in accordance with Table 7.4.1-1

7.12.7.6—Bearing Resistance

The nominal bearing resistance of a connected part shall be determined as follows:

$$R_n = \frac{d_e t F_{tu}}{1.5} \leq 1.33 D t F_{tu} \quad (7.12.7.6-1)$$

where:

- d_e = distance from the center of the pin to the edge of the part in the direction of force (in.)
- t = thickness of the connected part (in.)
- F_{tu} = tensile ultimate strength of the connected part (ksi)
- D = nominal diameter of the pin (in.)

7.12.7.7—Combined Shear and Flexure

For pins subjected to shear and flexure:

$$\left(\frac{P_u}{\phi R_n} \right)^3 + \left(\frac{M_u}{\phi M_n} \right) \leq 1.0 \quad (7.12.7.7-1)$$

where:

- P_u = shear force on the pin due to the factored loads (kip)
- R_n = nominal shear resistance of the pin (kip)
- M_u = moment on the pin due to the factored loads (k-in.)
- M_n = nominal flexural resistance of the pin (k-in.)

7.13—PROVISIONS FOR STRUCTURE TYPES

7.13.1—Deck Superstructures

7.13.1.1—General

The provisions of this Article shall apply to the design of bridges that use an aluminum deck that is connected to the superstructure with slip-critical connections. The aluminum deck shall be considered an integral part of the bridge superstructure and shall participate in resisting global force effects on the bridge. Connections between the deck and the main structural members shall be designed for interaction effects specified in Article 9.4.1.

C7.13.1.1

Aluminum decks transfer the load from vehicles' tires to the bridge superstructure.

For decks that act compositely with the bridge girders, this load transfer can be thought of as three systems:

- System 3 transfers the load from the tire patch on the top flange of the deck to the ribs that support the top flange. This load causes bending in the top flange.
- System 2 transfers the load transverse to traffic to the bridge girders. This load creates transverse forces in the top and bottom flanges and ribs of the deck.

- System 1 transfers the load in the direction of traffic in participation with the bridge girders to the bridge supports. This load causes longitudinal axial force in the deck.

7.13.1.2—Equivalent Strips

For decks with continuous top and bottom flanges, the equivalent strip used for analysis in accordance with Article 4.6.2.1 shall be as determined for cast-in-place concrete decks.

SECTION 8

WOOD STRUCTURES

Commentary is opposite the text it annotates.

8.1—SCOPE

This Section specifies design requirements for structural components made of sawn lumber products, stressed wood, glued laminated timber, wood piles, and mechanical connections.

8.2—DEFINITIONS

Adjusted Design Value—Reference design value multiplied by applicable adjustment factors.

Beams and Stringers (B&S)—Beams and stringers are rectangular pieces that are 5.0 or more in. thick (nominal), with a depth more than 2.0 in. (nominal) greater than the thickness. B&S are graded primarily for use as beams, with loads applied to the narrow face.

Bent—Type of pier consisting of two or more columns or column-like components connected at their top ends by a cap, strut, or other component holding them in their correct positions.

Bonded Reinforcement—Reinforcing material that is continuously attached to a glulam beam through adhesive bonding.

Bumper Lamination—Sacrificial wood lamination continuously bonded to the outer face of reinforcement to protect the reinforcement from damage or fire, or for visual appearance. The bumper lam is an option, not a requirement.

Cap—Sawn lumber or glulam component placed horizontally on an abutment or pier to distribute the live load and dead load of the superstructure. Also, a metal, wood, or mastic cover to protect exposed wood end grain from wetting.

Combination Symbol—Product designation used by the structural glued laminated timber industry; see AITC 117.

Conventional Lamstock—Solid sawn wood laminations with a net thickness of 2.0 in. or less, graded either visually or through mechanical means, finger-jointed and face-bonded to form a glulam per ASTM D7199.

Crib—Structure consisting of a foundation grillage and a framework providing compartments that are filled with gravel, stones, or other material satisfactory for supporting the structure to be placed thereon.

Decking—Subcategory of dimension lumber, graded primarily for use with the wide face placed flatwise.

Delamination—Adhesive failure causing the separation of laminations.

Development Length—Length of the bond line along the axis of the beam required to develop the design tensile strength of the reinforcement.

Diaphragm—Blocking between two main longitudinal beams consisting of solid lumber, glued laminated timber, or steel cross bracing.

Dimension Lumber—Lumber with a nominal thickness of from 2.0 up to but not including 5.0 in. and having a nominal width of 2.0 in. or more.

Dowel—Relatively short length of round metal bar used to interconnect or attach two wood components in a manner to minimize movement and displacement.

Dressed Lumber—Lumber that has been surfaced by a planing machine on one or more sides or edges.

Dry—Condition of having a relatively low moisture content, i.e., not more than 19 percent for sawn lumber and 16 percent for glued laminated timber.

E-Glass—Low-alkali (borosilicate glass) electrical grade glass fiber commonly used by the composite industry for the manufacture of FRP composites.

Fiber-Reinforced Polymer (FRP)—Any material consisting of at least two distinct components: reinforcing fibers and a binder matrix (a polymer). The reinforcing fibers are permitted to be synthetic (e.g. glass), metallic, or natural (e.g. bamboo), and are permitted to be long and continuously oriented or short and randomly oriented. The binder matrix is permitted to be either thermoplastic (e.g. polypropylene or nylon) or thermosetting (e.g. epoxy or vinyl-ester).

Frame Bent—Type of framed timber substructure.

Grade—Designation of the material quality of a manufactured piece of wood.

Grade Mark—Identification of lumber with symbols or lettering to certify its quality or grade.

Grain—Direction, size, arrangement, appearance, or quality of the fibers in wood or lumber.

Green Wood—Freshly sawn or undried wood. Wood that has become completely wet after immersion in water would not be considered green but may be said to be in the green condition.

Hardwood—Generally one of the botanical groups of trees that have broad leaves or the wood produced by such trees. The term does not refer to the actual hardness of the wood.

Horizontally Laminated Timber—Laminated wood in which the laminations are arranged with their wider dimension approximately perpendicular to the direction of applied transverse loads.

Laminate—Product made by bonding together two or more layers (laminations) of material or materials.

Laminated Wood—An assembly made by bonding layers of veneer or lumber with an adhesive, nails, or stressing to provide a structural continuum so that the grain of all laminations is essentially parallel.

Laminating—Process of bonding laminations together with adhesive, including the preparation of the laminations, preparation and spreading of adhesive, assembly of laminations in packages, application of pressure, and curing.

Lamination—Full-width and full-length layer contained in a component bonded together with adhesive. The layer itself may be composed of one or several wood pieces in width or length.

Machine Evaluated Lumber (MEL)—Mechanically graded lumber certified as meeting the criteria of a specific commercial grading system.

Machine Stress-Rated (MSR) Lumber—Mechanically graded lumber certified as meeting the criteria of a specific commercial grading system.

Mechanically Graded Lumber—Solid sawn lumber graded by mechanical evaluation in addition to visual examination.

Modulus of Rupture (MOR)—Maximum stress at the extreme fiber in bending, calculated from the maximum bending moment on the basis of an assumed stress distribution.

Moisture Content—Indication of the amount of water contained in the wood, usually expressed as a percentage of the weight of the oven-dry wood.

NDS®—*National Design Specification® for Wood Construction* by the American Forest and Paper Association.

NELMA—Grading rules by Northeastern Lumber Manufacturers Association.

NLGA—Grading rules by National Lumber Grades Authority.

Net Size—Size used in design to calculate the resistance of a component. Net size is close to the actual dry size.

Nominal Size—As applied to timber or lumber, the size by which it is specified and sold; often differs from the actual size.

NSLB—Grading rules by Northern Softwood Lumber Bureau. Note: NSLB merged with NELMA.

Oil-Borne Preservative—Preservative that is introduced into wood in the form of an oil-based solution.

Plank—Broad board, usually more than 1.0 in. thick, laid with its wide dimension horizontal and used as a bearing surface or riding surface.

Posts and Timber (P&T)—Posts and timbers pieces with a square or nearly square cross section, 5.0 by 5.0 in. (nominal) and larger, with the width not more than 2.0 in. (nominal) greater than the thickness. Lumber in the P&T size classification is graded primarily for resisting axial loads.

Preservative—Any substance that is effective in preventing the development and action of wood-decaying fungi, borers of various kinds, and harmful insects.

Reinforcement (for Glulam)—Any material that is not a conventional lamstock lumber whose mean (ultimate) longitudinal unit strength exceeds 20 ksi for tension and compression, and whose mean tension and compression modulus of elasticity exceeds 3,000 ksi. Acceptable reinforcing materials include but are not restricted to fiber-reinforced polymer (FRP) plates and bars, and metallic plates and bars.

Reference Design Value—Allowable stress value or modulus of elasticity specified in the *NDS*®.

Rough Sawn Lumber—Lumber that has not been dressed but that has been sawn, edged, and trimmed.

Sawn Lumber—Product of a sawmill not further manufactured other than by sawing, resawing, passing lengthwise through a standard planing mill, drying, and cross-cutting to length.

Sawn Timbers—Lumber that is nominally 5.0 in. or more in least dimension.

Softwood—Generally, one of the conifers or the wood produced by such trees. The term does not refer to the actual hardness of the wood.

SPIB—Grading rules by Southern Pine Inspection Bureau.

Stress Grades—Lumber grades having assigned working stress and modulus of elasticity in accordance with accepted principles of resistance grading.

Structural Glued Laminated Timber (Glulam)—Engineered, stress-rated product of a timber laminating plant comprised of assemblies of specially selected and prepared wood laminations securely bonded together with adhesives. The grain of all laminations is approximately parallel longitudinally. Glued laminated timber is permitted to be comprised of pieces end-joined to form any length, of pieces placed or bonded edge-to-edge to make any width, or of pieces bent to curved form during bonding.

Structural Lumber—Lumber that has been graded and assigned design values based on standardized procedures to ensure acceptable reliability.

Tension Reinforcement—Reinforcement placed on the tension side of a flexural member on the first glue-line or on the face of the beam.

Vertically Laminated Timber—Laminated wood in which the laminations are arranged with their wider dimension approximately parallel to the direction of load.

Visually Graded Lumber—Structural lumber graded solely by visual examination.

Waterborne Preservative—Preservative that is introduced into wood in the form of a water-based solution.

WCLIB—Grading rules by West Coast Lumber Inspection Bureau.

Wet-Use—Use conditions where the moisture content of the wood in service exceeds 16 percent for glulam and 19 percent for sawn lumber.

WWPA—Grading rules by Western Wood Products Association.

8.3—NOTATION

A	=	parameter for beam stability (8.6.2)
A_b	=	bearing area (in. ²) (8.8.3)
A_g	=	gross cross-sectional area of the component (in. ²) (8.8.2)
A_n	=	net cross-sectional area of the component (in. ²) (8.9)
a	=	coefficient (8.4.4.5)
B	=	parameter for compression (8.8.2)
b	=	width of the glued laminated timber component; thickness of lumber component (see Figure 8.3-1) (in.) (8.4.4.5)
C_b	=	bearing factor (8.8.3)
C_c	=	curvature factor (8.4.1.2)
C_d	=	deck factor (8.4.4.1) (8.4.4.8)
C_F	=	size factor (8.4.4.1) (8.4.4.4)
C_{fu}	=	flat use factor (8.4.4.1) (8.4.4.6)
C_i	=	incising factor (8.4.4.1) (8.4.4.7)
C_{KF}	=	format conversion factor (8.4.4.1) (8.4.4.2)
C_L	=	beam stability factor (8.6.2)
C_M	=	wet service factor (8.4.4.1) (8.4.4.3)
C_P	=	column stability factor (8.8.2)
C_V	=	volume factor (8.4.4.1) (8.4.4.5)
C_λ	=	time effect factor (8.4.4.1) (8.4.4.9)
c	=	coefficient (8.8.2)
d	=	depth of the beams or stringers or width of the dimension lumber component (8.4.4.4) or glulam depth (8.4.4.5) as shown in Figure 8.3-1 (in.) (8.4.1.1.1)
E	=	adjusted modulus of elasticity (ksi) (8.4.4.1)
E_o	=	reference modulus of elasticity (ksi) (8.4.1.1.4) (8.4.4.1)
$E_{o\text{ axial}}$	=	modulus of elasticity, axially loaded (8.4.1.2.3)
E_{vo}	=	modulus of elasticity, y-y axis (8.4.1.2.3)
E_{xo}	=	modulus of elasticity, x-x axis (8.4.1.2.3) (8.4.1.3.4)
E_{yo}	=	modulus of elasticity, y-y axis (8.4.1.2.3)
F	=	adjusted design value (ksi) (8.4.4.1)
F_b	=	adjusted design value in flexure (ksi) (8.4.4.1)
F_{bo}	=	reference design value of wood in flexure (ksi) (8.4.1.1.4) (8.4.4.1)
F_{by-y}	=	bending about the y-y axis (8.4.1.3.1)
F_{bvo}	=	extreme fiber in bending, y-y axis (8.4.1.2.3)
F_{bx}	=	tabulated design values for bending about the x-x axis (8.4.1.2.3)
F_{bxo}	=	extreme fiber in bending, x-x axis (8.4.1.2.3)
F_{bxo}^+	=	extreme fiber in bending, tension zone stressed in tension (8.4.1.3.4)
F_{bxo}^-	=	extreme fiber in bending, compression zone stressed in tension (8.4.1.3.4)
F_{byo}	=	extreme fiber in bending, y-y axis (8.4.1.2.3)
F_c	=	adjusted design value of wood in compression parallel to grain (ksi) (8.4.4.1) (8.4.1.3.1)
$F_{c\perp}$	=	compression perpendicular to grain (8.4.1.3.1)
F_{ce}	=	Euler buckling stress (8.8.2)
F_{co}	=	reference design value of wood in compression parallel to grain (ksi) (8.4.1.1.4) (8.4.4.1)
F_{cp}	=	adjusted design value of wood in compression perpendicular to grain (ksi) (8.4.4.1)
F_{cpo}	=	reference design value of wood in compression perpendicular to grain (ksi) (8.4.1.1.4) (Table 8.4.1.3.4-1) (8.4.4.1)
F_{epo}	=	compression perpendicular to grain, y-y axis (8.4.1.2.3)
F_o	=	reference design value (ksi) (8.4.4.1)
F_t	=	adjusted design value of wood in tension (ksi) (8.4.1.3.1) (Table 8.4.1.3.4-1) (8.4.4.1)
F_{to}	=	reference design value of wood in tension (ksi) (8.4.1.1.4) (8.4.4.1)
F_v	=	adjusted design value of wood in shear (ksi) (8.4.1.1.4) (8.4.1.3.1) (Table 8.4.1.3.4-1) (8.4.4.1)
F_{vo}	=	reference design value of wood in shear (ksi) (8.4.1.1.4) (8.4.4.1)

allowable stress design (ASD) and provides format conversion factors for use of these values with the load and resistance factor design (LRFD) methodology. To facilitate the direct use of the values developed by the wood products industry and included in the *NDS*[®], the same format has been adopted for AASHTO LRFD design.

Reference design values for tension-reinforced glulams have been developed following procedures in ASTM D7199 and AC 280 (ICC-ES).

8.4.1.1—Sawn Lumber

8.4.1.1.1—General

Sawn lumber shall comply with the requirements of AASHTO M 168.

When solid sawn beams and stringers are used as continuous or cantilevered beams, the grading provisions applicable to the middle third of the length shall be applied to at least the middle two thirds of the length of pieces to be used as two-span continuous beams and to the entire length of pieces to be used over three or more spans or as cantilevered beams.

8.4.1.1.2—Dimensions

Structural calculations shall be based on the actual net dimensions for the anticipated use conditions.

Dimensions stated for dressed lumber shall be the nominal dimensions. Net dimensions for dressed lumber shall be taken as 0.5 in. less than nominal, except that the net width of dimension lumber exceeding 6.0 in. shall be taken as 0.75 in. less than nominal.

For rough-sawn, full-sawn, or special sizes, the actual dimensions and moisture content used in design shall be indicated in the contract documents.

C8.4.1.1.2

These net dimensions depend on the type of surfacing, whether dressed, rough-sawn, or full-sawn.

The designer should specify surface requirements on the plans. Rough-sawn lumber is typically 0.125 in. larger than standard dry dressed sizes, associated with the F_{bo} value in Table 8.4.1.1.4-2 and full-sawn lumber, which is not widely used, is cut to the same dimensions as the nominal size. In both of the latter cases, thickness and width dimensions are variable, depending on the sawmill equipment. Therefore, it is impractical to use rough-sawn or full-sawn lumber in a structure that requires close dimensional tolerances.

For more accurate dimensions, surfacing can be specified on one side (S1S), two sides (S2S), one edge (S1E), two edges (S2E), combinations of sides and edges (e.g., S1S1E, S2S1E, S1S2E), or all sides (S4S).

8.4.1.1.3—Moisture Content

The moisture content of dimension lumber shall not be greater than 19 percent at the time of installation.

8.4.1.1.4—Reference Design Values

Reference design values for visually graded sawn lumber shall be as specified in Table 8.4.1.1.4-1.

Reference design values for mechanically graded dimension lumber shall be as specified in Table 8.4.1.1.4-2.

Unless otherwise indicated, reference design value in flexure for dimension lumber and posts and timbers shall

C8.4.1.1.4

apply to material where the load is applied to either the narrow or wide face. Reference design value in flexure for decking grades shall apply only with the load applied to the wide face.

Values for specific gravity, G , shear parallel to grain, F_v , and compression perpendicular to grain, $F_{c\perp}$, for mechanically graded dimension lumber shall be taken as specified in Table 8.4.1.1.4-3. For species or species groups not given in Table 8.4.1.1.4-3, the G , F_v , and $F_{c\perp}$ values for visually graded lumber may be used.

Reference design values for lumber grades not given in Table 8.4.1.1.4-1 and Table 8.4.1.1.4-2 shall be obtained from the *National Design Specification® (NDS®) for Wood Construction*.

Where the E_o or F_{to} values shown on a grade stamp differ from Table 8.4.1.1.4-2 values associated with the F_{bo} on the grade stamp, the values on the stamp shall be used in design, and the F_{co} value associated with the F_{bo} value in Table 8.4.1.1.4-2 shall be used.

For machine evaluated lumber (MEL) commercial grades M-17, M-20, and M-27, F_{co} , requires qualification and quality control shall be required.

Reference design values specified in Table 8.4.1.1.4-2 shall be taken as applicable to lumber that will be used under dry conditions. For 2.0-in. to 4.0-in. thick lumber, the dry dressed sizes shall be used regardless of the moisture content at the time of manufacture or use.

In calculating design values in Table 8.4.1.1.4-2, the natural gain in strength and stiffness that occurs as lumber dries has been taken into consideration as well as the reduction in size that occurs when unseasoned lumber shrinks. The gain in load carrying capacity due to increased strength and stiffness resulting from drying more than offsets the design effect of size reductions due to shrinkage.

For any given bending design value, F_{bo} , the modulus of elasticity, E_o , and tension parallel to grain, F_{to} , design value may vary depending upon species, timber source, or other variables. The E_o and F_{to} values included in the F_{bo} - E_o grade designations in Table 8.4.1.1.4-2 are those usually associated with each F_{bo} level. Grade stamps may show higher or lower values if machine rating indicates the assignment is appropriate.

Higher G values may be claimed when (a) specifically assigned by the rules writing agency or (b) when qualified by test, quality controlled for G , and provided for on the grade stamp. When a different G value is provided on the grade stamp, higher F_v and $F_{c\perp}$ design values may be calculated in accordance with the grading rule requirements.

Table 8.4.1.1.4-1—Reference Design Values for Visually Graded Sawn Lumber

Species and Commercial Grade	Size Classification	Design Values (ksi)						Grading Rules Agency

8.4.1.2—Structural Glued Laminated Timber (Glulam)**8.4.1.2.1—General**

Structural glued laminated timber shall be manufactured using wet-use adhesives and shall comply with the requirements of ANSI A190.1. Glued laminated timber may be manufactured from any lumber species, provided that it meets the requirements of ANSI A190.1 and is treatable with wood preservatives in accordance with the requirements of Article 8.4.3.

The contract documents shall require that each piece of glued laminated timber be distinctively marked and provided with a Certificate of Conformance by an accredited inspection and testing agency, indicating that the requirements of ANSI A190.1 have been met and that straight or slightly cambered bending members have been stamped TOP on the top at both ends so that the natural camber, if any, shall be positioned opposite to the direction of applied loads.

C8.4.1.2.1

When wet-use adhesives are used, the bond between the laminations, which is stronger than the wood, will be maintained under all exposure conditions. Dry-use adhesives will deteriorate under wet conditions. For bridge applications, it is not possible to ensure that all areas of the components will remain dry. ANSI A190.1 requires the use of wet-use adhesives for the manufacture of structural glued laminated timber.

Industrial appearance grade, as defined in AITC 110, *Standard Appearance Grades for Structural Glued Laminated Timber*, shall be used, unless otherwise specified.

Structural glued laminated timber is available in four standard appearance grades: framing, industrial, architectural, and premium. Architectural and premium grades are typically planed or sanded, and exposed irregularities are filled with a wood filler that may crack and dislodge under exterior exposure conditions. Framing grade is surfaced hit-or-miss to produce a timber with the same net width as standard lumber for concealed applications where matching the width of framing lumber is important. Framing grade is not typically used for bridge applications. In addition to the four standard appearance grades, certain manufacturers will use special surfacing techniques to achieve a desired look, such as a rough sawn look. Individual manufacturers should be contacted for details.

8.4.1.2.2—Dimensions

Dimensions stated for glued laminated timber shall be taken as the actual net dimensions.

In design, structural calculations shall be based on the actual net dimensions. Net width of structural glued laminated timber shall be as specified in Table 8.4.1.2.2-1 or other dimensions as agreed upon by buyer and seller.

C8.4.1.2.2

Structural glued laminated timber can be manufactured to virtually any shape or size. The most efficient and economical design generally results when standard sizes are used. Acceptable manufacturing tolerances are given in ANSI A190.1.

The use of standard sizes constitutes good practice and is recommended whenever possible. Nonstandard sizes should only be specified after consultation with the laminator.

Southern Pine timbers are typically manufactured from 1.375-in.-thick laminations, while timbers made from Western Species and Hardwoods are commonly manufactured from 1.5-in.-thick laminations. Curved members may be manufactured from thinner laminations depending on the radius of curvature. Radii of curvature of less than 27.0 ft, 6.0 in. normally require the use of thinner laminations.

Table 8.4.1.2.2-1—Net Dimensions of Glued Laminated Timber

Nominal Width of Laminations (in.)	Western Species Net Finished Dimension (in.)	Southern Pine Net Finished Dimension (in.)
3	2 1/8 or 2 1/2	2 1/8 or 2 1/2
4	3 1/8	3.0 or 3 1/8
6	5 1/8	5.0 or 5 1/8
8	6 3/4	6 3/4
10	8 3/4	8 3/4
12	10 3/4	10 1/2
14	12 1/4	12.0
16	14 1/4	14.0

The total glulam net depth shall be taken as the product of the thickness of the laminations and the number of laminations.

Reference design values for combinations not given in Table 8.4.1.2.3-1 or Table 8.4.1.2.3-2 shall be obtained from ANSI 117.

Table 8.4.1.2.3.1—Reference Design Values, ksi, for Structural Glued Laminated Softwood Timber Combinations (members stressed primarily in bending)

8.4.1.3—Tension-Reinforced Glulams

8.4.1.3.1—General

Tension-reinforced glulams shall incorporate a continuous reinforcement material placed on the tension side of a flexural member to increase its flexural bending strength and stiffness. Reinforcement may be any material that is not a conventional lamstock whose mean longitudinal unit strength exceeds 20 ksi for tension and compression mean ultimate strength, and whose mean tension and compression modulus of elasticity exceeds 3,000 ksi, when placed into a glulam timber. Acceptable reinforcing materials include but are not restricted to: fiber-reinforced polymer (FRP) plates and bars using E-glass fibers (GFRP) or carbon fibers (CFRP), and metallic plates and bars.

The reinforced ratio, ρ , shall be determined as the cross-sectional area of tension reinforcement divided by cross-sectional area of beam above the center of gravity of tension reinforcement, expressed in percent. Typical reinforcement ratios and modulus of elasticity values for various types of reinforcement given in Table 8.4.1.3.1-1 shall apply.

Table 8.4.1.3.1-1—Typical Reinforcement Ratios

	Reinforcement Material			
	E-Glass FRP	Aramid FRP	Carbon FRP	Steel Plate
MOE (ksi)	6,000	10,000	20,000	30,000
Min. $\rho\%$	1	0.6	0.3	0.2
Typical $\rho\%$	2	1.2	0.6	0.4
Max. $\rho\%$	3	1.8	0.9	0.6

Tension-reinforced glued laminated timber shall be manufactured using wet-use adhesives in accordance with applicable provisions of ANSI A190.1, and shall comply with the requirements listed in Article 8.4.1.2, except as described in detail in ASTM D7199. The additional requirements cited in ASTM D7199 to be investigated shall include bond strength and durability requirements for the tension reinforcement, preservative treatment, volume factor, and fatigue considerations.

8.4.1.3.2—Dimensions

Dimensions stated for tension-reinforced glued laminated timber shall be taken as the actual net dimensions.

In design, structural calculations shall be based on the actual net dimensions. Net width of tension-reinforced structural glued laminated timber shall be as specified in Table 8.4.1.2.2-1 or other dimensions as agreed upon by buyer and seller. The total reinforced glulam net depth shall be the sum of the thicknesses of all laminations including the thickness of the tension reinforcement lamination(s).

C8.4.1.3.1

The determination of reinforcement ratio, ρ , is analogous to that used for reinforced concrete.

The scope of ASTM D7199 pertains to the analysis of FRP-glulams in bending. The addition of FRP reinforcement in the tension region of the glulam does not require new test or analytical methods to determine the secondary design properties (shear, compression perpendicular to grain, tension parallel to grain, compression parallel to grain, etc.). These properties are determined for glulam layups following ASTM D3737.

Tension-reinforced glulam beams subject to axial compression loads are outside the scope of this specification. This specification does not cover unbonded reinforcement (i.e. material not continuously bonded to the beam), prestressed reinforcement (i.e. material pretensioned before being bonded or anchored to the beam), nor shear reinforcement (i.e. material intended to increase the shear strength of the beam).

ASTM D7199 also provides a mechanics-based approach for predicting the mechanical properties of tension-reinforced glulams, and may be used by engineers who have applications with unique reinforcement requirements. ASTM D7199 addresses methods to obtain bending properties parallel to grain about the x - x axis, $MOR_{5\%}$ and MOE , for horizontally laminated reinforced glulam beams. Secondary properties such as bending about the y - y axis, F_{by-y} , shear parallel to grain, F_v , tension parallel to grain, F_t , compression parallel to grain, F_c , and compression perpendicular to grain, $F_{c\perp}$, are determined following methods described in ASTM D3737 or testing according to other applicable methods such as ASTM D198 or ASTM D143.

The gross section properties shall be calculated using the net depth and the net width.

8.4.1.3.3—Fatigue

Except as noted herein, tension reinforcement shall extend the full length of the beam or girder and be confined by the supports.

For E-glass FRP reinforcement produced using the pultrusion process, beams that satisfy the requirements for design for static loads specified herein may be considered to have adequate fatigue design capacity. For reinforcements other than pultruded E-glass reinforcements, coupon-level fatigue testing of the reinforcing material per ASTM D3479 or a similar procedure shall be required to develop the strength-load cycle relationship for the reinforcing material. A minimum of three representative FRP samples shall be tested to establish the strength-load cycle relationship. This strength-load cycle relationship shall be the basis for checking fatigue capacity of the FRP under specific end-use environment.

Full-scale fatigue testing shall be required where partial-length reinforcement is used to evaluate the effectiveness of reinforcement end-confinement detail. The reinforcement termination for partial-length FRP reinforcement shall be confined over the length at least equal to the width of the reinforcing material. Unconfined, partial-length reinforcement shall not be permitted in bridge applications where fatigue loading exists.

Full-scale fatigue testing shall be required on FRP-glulam beams where the allowable stress is more than 75 percent greater than conventional glulam ($F_b > 4,000$ psi).

Where fatigue is a design consideration, the reinforcement used shall not increase the $MOR_{5\%}$ of the beam by more than 75 percent relative to the strength of the unreinforced beam.

8.4.1.3.4—Reference Design Values for Tension-Reinforced Glulams

Reference design values for tension-reinforced glulams shall be taken as specified in Table 8.4.1.3.4-1 for beams with no bumper-lams. For the beam lay-ups given in Table 8.4.1.3.4-1, the volume factor shall be taken equal to 1. The values are for dry use, with adjustment factors given in Article 8.4.4.3, and shall be used in the same manner as conventional glulam design values except as specified in

C8.4.1.3.3

The research that was performed utilized confinement achieved by end-bearing support. Confinement proposed by alternative methods may require full-scale testing.

Under the specified conditions, testing has shown that the fatigue resistance of tension-reinforced glulam beams is similar to that of conventional glulam beams. These tests have included both fatigue and hygrothermal cyclic tests (Davids et al., 2005 and 2008).

For pultruded E-glass FRP reinforcement, full-scale tension-reinforced glulam beam flexural fatigue tests, where the reinforcement extends the full length of the beam, have shown that the reinforced beams properly designed for static loads will have fatigue design capacity in excess of two million constant-amplitude sinusoidal cycles. Each of these cycles applied an extreme fiber stress range starting from the dead load bending stress to a bending stress equivalent to the full allowable design stress. Under these conditions, no degradation in bending strength or stiffness has been observed.

Full-scale fatigue testing has been performed on FRP-reinforced glulam beams, considering both full-length and partial-length reinforced glulams. These tests were conducted for tension-reinforced beams where the allowable design stresses were up to 75 percent greater than the conventional unreinforced glulam. This testing has shown that premature failure due to fatigue in FRP-glulams is not a concern if (1) the FRP reinforcement has been fatigue-tested at the coupon level and (2) the FRP tension reinforcement runs for the full length of the glulam over the supports. For partial-length reinforcement (where the FRP is terminated before the supports) and for FRP-glulams where the allowable stress is more than 75 percent greater than conventional glulam ($F_b > 4,000$ psi), full-scale fatigue testing is required. Guidance on performing such tests can be found in Davids et al. (2005 and 2008). In fatigue tests where $MOR_{5\%}$ has been increased by more than 75 percent, flexural compression and shear failures have been observed in addition to flexural tension failures.

FRP coupon fatigue design data should be available from reinforced beam manufacturers or FRP suppliers. The vast majority of applications will not require full-scale fatigue testing of beams.

C8.4.1.3.4

Axial compression is outside the scope of this specification. For tension-reinforced glulam subjected to axial compression, ASTM D3737 provides a method to account for the neutral axis (NA) change in unbalanced layups. FRP stiffness and shift in the neutral axis shall be accounted for when developing axial compression design values. Bending properties about the y-y axis may be

Article 8.4.1.3. These design values shall be used with the overall gross section properties of the beam, including the reinforcement.

conservatively taken as those of the wood portion of the beam, neglecting the reinforcement.

Analysis has shown that with the level of FRP extreme fiber tension reinforcement typically envisioned (up to 3 percent for GFRP or 1 percent for CFRP), the maximum shear stress at the reinforced beam neutral axis is very similar to that of an unreinforced rectangular section. In addition, under the same conditions, the shear stress at the FRP–wood interface is always significantly smaller than the shear stress at the reinforced beam neutral axis.

Table 8.4.1.3.4-1—Reference Design Values for Tension-Reinforced Structural Glued Laminated Douglas Fir Combinations (ksi)¹

Combination Symbol	Species (Outer/Core)	Bending about x-x Axis					
		Extreme Fiber in Bending		Compression Perpendicular to Grain		Shear	Modulus of Elasticity $E_{xo} \times 10^3$
		Tension Zone Stressed in Tension $F_{txo} +$	Compression Zone Stressed in Tension $F_{txo} -$	Tension Face	Compression Face		
				F_{cpo}	F_{cpo}	F_{vxo}	
30F-1.9E							
30F-V1R	DF/DF	3.000	1.900	0.56	0.56	0.265	1.9

34F-V1R	DF/DF	3.400	2.100	0.56	0.56	0.265	2.2

¹ Species other than Douglas Fir may be used if evaluated in accordance with ASTM D7199.

8.4.1.3.5—Volume Effect

Volume factors for the tension-reinforced glulams listed in Table 8.4.1.3.4-1 shall be taken equal to 1 except where the unreinforced compression zone is stressed in tension. In this latter case, the volume factor used in conventional glulams shall apply for the determination of this value.

C8.4.1.3.5

The addition of tension reinforcement diminishes the volume effect in glulams, and with enough reinforcement in tension, the volume effect disappears (Lindyberg, 2000). The tension reinforcement that is necessary to eliminate the volume effect varies with the wood species and grade, as well as the type of reinforcement used (e.g., E-glass, carbon, or Aramid FRP). For example, western species glulam reinforced with E-glass FRP in tension, approximately 1.5–3 percent FRP by volume will eliminate the volume effect (Lindyberg, 2000). For the particular glulams listed in Table 8.4.1.3.4-1, the E-glass tension reinforcement ratio is over 3 percent, and the corresponding volume factor is equal to 1. If the tension reinforcement ratio is reduced, the actual volume factor is a function of the reinforcement ratio and the reinforcement longitudinal stiffness. A numerical model that predicts the volume factor for reinforced glulams for any layup and type of reinforcement is available (Lindyberg, 2000).

8.4.1.3.6—Preservative Treatment

Designers shall specify that the effect of preservative treatment on the properties of the FRP reinforcement and on the strength and durability of the FRP–wood bond shall be evaluated as described in ASTM D7199. Preservative treatment shall be applied after bonding of the reinforcement. GFRP reinforced beams shall not be post-treated with CCA preservatives.

C8.4.1.3.6

CCA preservative has been shown to cause severe cracking in the E-glass reinforcement.

8.4.1.4—Piles

Wood piles shall comply with the requirements of AASHTO M 168.

Reference design values for round wood piles shall be as specified in Table 8.4.1.4-1.

C8.4.1.4

The reference design values for wood piles are based on wet-use conditions.

Table 8.4.1.4-1—Reference Design Values for Piles, ksi

Species	F_{co}	F_{bo}	F_{cpo}	F_{vo}	E_o
Pacific Coast Douglas Fir ¹	1.25	2.45	0.23	0.115	1500
Red Oak ²	1.10	2.45	0.35	0.135	1250
Red Pine ³	0.90	1.90	0.155	0.085	1280
Southern Pine ⁴	1.20	2.40	0.25	0.11	1500

¹ For connection design, use Douglas Fir–Larch reference design values.

² Red Oak reference strengths apply to Northern and Southern Red Oak.

³ Red Pine reference strengths apply to Red Pine grown in the U.S. For connection design, use Northern Pine reference design values.

⁴ Southern Pine reference strengths apply to Loblolly, Longleaf, Shortleaf, and Slash Pine.

8.4.2—Metal Fasteners and Hardware**8.4.2.1—General**

Structural metal, including shapes, plates, bars, and welded assemblies, shall comply with the applicable material requirements of Section 6.

8.4.2.2—Minimum Requirements**8.4.2.2.1—Fasteners**

Bolts and lag screws shall comply with the dimensional and material quality requirements of ANSI/ASME B18.2.1, *Square and Hex Bolts and Screws—Inch Series*. Strengths for low-carbon steel bolts, Grade 1 through Grade 8, shall be as specified in Society of Automotive Engineers (SAE) specification SAE-429, *Mechanical and Material Requirements for Externally Threaded Fasteners*. Bolt and lag screw grades not given in SAE-429 shall have a minimum tensile yield strength of 33.0 ksi.

8.4.2.2.2—*Prestressing Bars*

Prestressing bars shall comply with the requirements of AASHTO M 275M/M 275 (ASTM A722/A722M) and the applicable provisions of Section 5.

8.4.2.2.3—*Split Ring Connectors*

Split ring connectors shall be manufactured from hot-rolled carbon steel complying with the requirements of SAE-1010. Each circular ring shall be cut through in one place in its circumference to form a tongue and slot.

8.4.2.2.4—*Shear Plate Connectors*

Shear plate connectors shall be manufactured from pressed steel, light-gauge steel, or malleable iron. Pressed steel connectors shall be manufactured from hot-rolled carbon steel meeting SAE-1010. Malleable iron connectors shall be manufactured in accordance with ASTM A47, Grade 32510.

Each shear plate shall be a circle with a flange around the edge, extending at right angles to the plate face from one face only.

8.4.2.2.5—*Nails and Spikes*

Nails and spikes shall be manufactured from common steel wire or high-carbon steel wire that is heat treated and tempered. When used in withdrawal-type connections, the shank of the nail or spike shall be annularly or helically threaded.

8.4.2.2.6—*Drift Pins and Bolts*

Drift pins and drift bolts shall have a minimum flexural yield strength of 30.0 ksi.

8.4.2.2.7—*Spike Grids*

Spike grids shall conform to the requirements of ASTM A47, Grade 32510, for malleable iron casting.

8.4.2.2.8—*Toothed Metal Plate Connectors*

Metal plate connectors shall be manufactured from galvanized sheet steel that complies with the requirements of ASTM A653, Grade A, or better, with the following minimum mechanical properties:

Yield Point	33.0 ksi
Ultimate Strength	45.0 ksi
Elongation in 2.0 in.	20 percent

8.4.2.3—Corrosion Protection

8.4.2.3.1—Metallic Coating

Except as permitted by this section, all steel hardware for wood components shall be galvanized in accordance with AASHTO M 232M/M 232 (ASTM A153/A153M) or cadmium plated in accordance with ASTM B696.

Except as otherwise permitted, all steel components, timber connectors, and castings other than malleable iron shall be galvanized in accordance with AASHTO M 111M/M 111 (ASTM A123/A123M).

8.4.2.3.2—Alternative Coating

Alternative corrosion protection coatings may be used when the demonstrated performance of the coating is sufficient to provide adequate protection for the intended exposure condition during the design life of the bridge. When epoxy coatings are used, minimum coating requirements shall comply with ASTM A775/A775M.

Heat-treated alloy components and fastenings shall be protected by an approved alternative protective treatment that does not adversely affect the mechanical properties of the material.

8.4.3—Preservative Treatment

8.4.3.1—Requirement for Treatment

All wood used for permanent applications shall be pressure impregnated with wood preservative in accordance with the requirements of AASHTO M 133.

Insofar as is practicable, all wood components should be designed and detailed to be cut, drilled, and otherwise fabricated prior to pressure treatment with wood preservatives. When cutting, boring, or other fabrication is necessary after preservative treatment, exposed, untreated wood shall be specified to be treated in accordance with the requirements of AASHTO M 133.

8.4.3.2—Treatment Chemicals

Unless otherwise approved, all structural components that are not subject to direct pedestrian contact shall be treated with oil-borne preservatives. Pedestrian railings and nonstructural components that are subject to direct pedestrian contact shall be treated with water-borne preservatives or oil-borne preservatives in light petroleum solvent.

C8.4.2.3.1

Galvanized nuts should be retapped to allow for the increased diameter of the bolt due to galvanizing.

Protection for the high-strength bars used in stress-laminated decks should be clearly specified. Standard hot-dip galvanizing can adversely affect the properties of high-strength post-tensioning materials. A lower-temperature galvanizing is possible with some high-strength bars. The manufacturer of the bars should be consulted on this issue.

C8.4.3.2

The oil-borne preservative treatments have proven to provide adequate protection against wood-attacking organisms. In addition, the oil provides a water repellent coating that reduces surface effects caused by cyclic moisture conditions. Water-borne preservative treatments do not provide the water repellency of the oil-borne treatment, and components frequently split and check, leading to poor field performance and reduced service life.

Direct pedestrian contact is considered to be contact that can be made while the pedestrian is situated anywhere in the access route provided for pedestrian traffic.

Treating of glued laminated timbers with water-borne preservatives after gluing is not recommended. Use of

water-borne treatments for glued laminated timber after gluing may result in excessive warping, checking, or splitting of the components due to post-treatment redrying.

8.4.3.3—Inspection and Marking

Preservative treated wood shall be tested and inspected in accordance with the requirements of AASHTO M 133. Where size permits, each piece of treated wood that meets treatment requirements shall be legibly stamped, branded, or tagged to indicate the name of the treater and the specification symbol or specification requirements to which the treatment conforms.

When requested, a certification indicating test results and the identification of the inspection agency shall be provided.

8.4.3.4—Fire Retardant Treatment

Fire retardant treatments shall not be applied unless it is demonstrated that they are compatible with the preservative treatment used, and the usable resistance and stiffness are reduced as recommended by the product manufacturer and applicator.

C8.4.3.4

Use of fire retardant treatments is not recommended because the large sizes of timber components typically used in bridge construction have inherent fire resistance characteristics. The pressure impregnation of wood products with fire retardant chemicals is known to cause certain resistance and stiffness losses in the wood. Resistance and stiffness losses vary with specific resistance characteristic (e.g., bending resistance; tension parallel to grain resistance); treatment process; wood species and type of wood product (e.g., solid sawn, glued laminated, or other).

8.4.4—Adjustment Factors for Reference Design Values

8.4.4.1—General

Adjusted design values shall be obtained by adjusting reference design values by applicable adjustment factors in accordance with the following equations:

$$F_b = F_{bo} C_{KF} C_M (C_F \text{ or } C_v) C_{fu} C_i C_d C_\lambda \quad (8.4.4.1-1)$$

$$F_v = F_{vo} C_{KF} C_M C_i C_\lambda \quad (8.4.4.1-2)$$

$$F_t = F_{to} C_{KF} C_M C_F C_i C_\lambda \quad (8.4.4.1-3)$$

$$F_c = F_{co} C_{KF} C_M C_F C_i C_\lambda \quad (8.4.4.1-4)$$

$$F_{cp} = F_{cpo} C_{KF} C_M C_i C_\lambda \quad (8.4.4.1-5)$$

$$E = E_o C_M C_i \quad (8.4.4.1-6)$$

where:

- F = applicable adjusted design values F_b , F_v , F_t , F_c , or F_{cp} (ksi)
 F_o = reference design values F_{bo} , F_{vo} , F_{to} , F_{co} , or F_{cpo} specified in Article 8.4 (ksi)
 C_{KF} = format conversion factor specified in Article 8.4.4.2

C_M	=	wet service factor specified in Article 8.4.4.3
C_F	=	size factor for visually graded dimension lumber and sawn timbers specified in Article 8.4.4.4
C_V	=	volume factor for structural glued laminated timber specified in Article 8.4.4.5
C_{fu}	=	flat-use factor specified in Article 8.4.4.6
C_i	=	incising factor specified in Article 8.4.4.7
C_d	=	deck factor specified in Article 8.4.4.8
C_λ	=	time effect factor specified in Article 8.4.4.9
E	=	adjusted modulus of elasticity (ksi)
E_o	=	reference modulus of elasticity specified in Article 8.4.1.1.4 (ksi)

8.4.4.2—Format Conversion Factor, C_{KF}

The reference design values in Tables 8.4.1.1.4-1, 8.4.1.1.4-2, 8.4.1.1.4-3, 8.4.1.2.3-1, 8.4.1.2.3-2, 8.4.1.3.4-1, and 8.4.1.4-1 and reference design values specified in the *NDS*[®] shall be multiplied by a format conversion factor, C_{KF} , for use with load and resistance factor design (LRFD). $C_{KF} = 2.5/\phi$, except for compression perpendicular to grain, which shall be obtained by multiplying the allowable stress by a format conversion factor of $C_{KF} = 2.1/\phi$.

C8.4.4.2

The conversion factors were derived so that LRFD design will result in same size member as the allowable stress design (ASD) specified in *NDS*[®]. For example, a rectangular component in flexure has to satisfy:

$$1.25 M_{DL} + 1.75 M_{LL} \leq \phi S F_{bo} C_{KF} C_M (C_F \text{ or } C_V) C_{fu} C_i C_d C_\lambda C_L \quad (\text{C8.4.4.2-1})$$

or:

$$(1.25 M_{DL} + 1.75 M_{LL}) / (\phi C_{KF} C_\lambda) \leq S F_{bo} C_M (C_F \text{ or } C_V) C_{fu} C_i C_d C_L \quad (\text{C8.4.4.2-2})$$

where:

M_{DL} = moment due to dead load
 M_{LL} = moment due to live load

Alternatively, the allowable stress design (ASD) has to satisfy:

$$M_{DL} + M_{LL} \leq S F_{bo} C_M (C_F \text{ or } C_V) C_{fu} C_i C_d C_D C_L \text{ or } (M_{DL} + M_{LL}) / (C_D) \leq S F_{bo} C_M (C_F \text{ or } C_V) C_{fu} C_i C_d C_L \quad (\text{C8.4.4.2-3})$$

Therefore:

$$(1.25 M_{DL} + 1.75 M_{LL}) / (\phi C_{KF} C_\lambda) = (M_{DL} + M_{LL}) / (C_D) \quad (\text{C8.4.4.2-4})$$

$$C_{KF} = [(1.25 M_{DL} + 1.75 M_{LL})(C_D)] / [(M_{DL} + M_{LL})(\phi C_\lambda)] \quad (\text{C8.4.4.2-5})$$

The format conversion factor is calculated assuming the ratio of M_{DL} and M_{LL} is 1:10, $\phi = 0.85$, $C_\lambda = 0.8$, and $C_D = 1.15$.

8.4.4.3—Wet Service Factor, C_M

The reference design values specified in Tables 8.4.1.1.4-1, 8.4.1.1.4-2, 8.4.1.1.4-3, 8.4.1.2.3-1, 8.4.1.2.3-2, 8.4.1.3.4-1, and 8.4.1.4-1 are for dry use conditions and shall be adjusted for moisture content using the wet service factor, C_M , specified below:

- For sawn lumber with an in-service moisture content of 19 percent or less, C_M shall be taken as 1.0.
- For glued laminated and tension-reinforced glued laminated (reinforced and unreinforced) timber with an in-service moisture content of 16 percent or less, C_M shall be taken as 1.0.
- Otherwise, C_M shall be taken as specified in Tables 8.4.4.3-1 for sawn lumber and Table 8.4.4.3-2 for reinforced and unreinforced glued laminated timber, respectively.

Reference design values for Southern Pine and Mixed Southern Pine sawn timbers 5 in. $\times$ 5 in. and larger shall be taken to apply to wet or dry use.

The wet service factors for reinforced and unreinforced glued laminated timber shall be the same.

Table 8.4.4.3-1—Wet Service Factor for Sawn Lumber, C_M

Nominal Thickness	$F_{bo}C_F \leq 1.15$ ksi	$F_{bo}C_F > 1.15$ ksi	F_{to}	$F_{co}C_F \leq 0.75$ ksi	$F_{co}C_F > 0.75$ ksi	F_{vo}	F_{cpo}	E_o
≤ 4 in.	1.00	0.85	1.00	1.00	0.80	0.97	0.67	0.90
> 4.0 in.	1.00	1.00	1.00	0.91	0.91	1.00	0.67	1.00

Table 8.4.4.3-2—Wet Service Factor for Glued Laminated Timber and Tension-Reinforced Glued Laminated Timber, C_M

F_{bo}	F_{vo}	F_{to}	F_{co}	F_{cpo}	E_o
0.80	0.875	0.80	0.73	0.53	0.833

8.4.4.4—Size Factor, C_F , for Sawn Lumber

The size factor, C_F , shall be 1.0 unless specified otherwise herein. For visually graded dimension lumber of all species except Southern Pine and Mixed Southern Pine, C_F shall be as specified in Table 8.4.4.4-1.

Reference design values for Southern Pine and Mixed Southern Pine dimension lumber have been size-adjusted; no further adjustment for size shall be applied.

For Southern Pine and Mixed Southern Pine dimension lumber wider than 12.0 in., the tabulated bending, compression, and tension parallel to grain design values, for the 12.0 in. depth, shall be multiplied by the size factor, $C_F = 0.9$.

C8.4.4.3

An analysis of in-service moisture content should be based on regional, geographic, and climatological conditions. In the absence of such analysis, wet-use conditions should be assumed.

Reduction for wet use is not required for Southern Pine and Mixed Southern Pine sawn timbers 5 in. $\times$ 5 in. and larger.

C8.4.4.4

C_F does not apply to mechanically graded lumber (MSR, MEL) or to structural glued laminated timber.

Tabulated design values for visually graded lumber of Southern Pine and Mixed Southern Pine species groups have already been adjusted for size. Further adjustment by the size factor is not permitted.

Table 8.4.4.4-1—Size Effect Factor, C_F , for Sawn Dimension Lumber

Grade	Width (in.)	F_{bo}		F_{to}	F_{co}	All Other Properties	
		Thickness					
		2.0 in. and 3.0 in.	4.0 in.	All	All		All
		Structural Light Framing: 2.0 in. $\times$ 2.0 in. through 4.0 in. $\times$ 4.0 in. Structural Joists and Planks: 2.0 in. $\times$ 5.0 in. through 4.0 in. $\times$ 16.0 in.					
	≤ 4	1.5	1.54	1.5	1.15	1.00	
Select Structural	5	1.4	1.4	1.4	1.1		
No. 1	6	1.3	1.3	1.3	1.1		
No. 2	8	1.2	1.3	1.2	1.05		
	10	1.1	1.2	1.1	1.0		
	12	1.0	1.1	1.0	1.0		
	≥ 14	0.9	1.0	0.9	0.9		

For sawn beams and stringers with loads applied to the narrow face and posts and timbers with loads applied to either face, F_{bo} shall be adjusted by C_F determined as:

- If $d \leq 12.0$ in., then

$$C_F = 1.0 \quad (8.4.4.4-1)$$

- If $d > 12.0$ in., then

$$C_F = \left(\frac{12}{d} \right)^{\frac{1}{9}} \quad (8.4.4.4-2)$$

where:

d = net width as shown in Figure 8.3-1

For beams and stringers with loads applied to the wide face, F_{bo} shall be adjusted by C_F as specified in Table 8.4.4.4-2.

Table 8.4.4.4-2—Size Factor, C_F , for Beams and Stringers with Loads Applied to the Wide Face

Grade	F_{bo}	E_o	Other Properties
Select Structural	0.86	1.00	1.00
No. 1	0.74	0.90	1.00
No. 2	1.00	1.00	1.00

8.4.4.5—Volume Factor, C_V , (Glulam)

For horizontally laminated glulam with loads applied perpendicular to the wide face of the laminations, F_{bo} shall be reduced by C_V , given below, when the depth, width, or length of a glued laminated timber exceeds 12.0 in., 5.125 in., or 21.0 ft, respectively:

$$C_V = \left[\left(\frac{12.0}{d} \right) \left(\frac{5.125}{b} \right) \left(\frac{21}{L} \right) \right]^a \leq 1.0 \quad (8.4.4.5-1)$$

where:

- d = depth of the component (in.)
- b = width of the component (in.) For layups with multiple piece laminations (across the width), b = width of widest piece. Therefore: $b \leq 10.75$ in.
- L = length of the component measured between points of contraflexure (ft)
- a = 0.05 for Southern Pine and 0.10 for all other species.

The volume factor, C_V , shall not be applied simultaneously with the beam stability factor, C_L ; therefore, the lesser of these factors shall apply.

The conventional glulam volume factor shall not be applied to tension-reinforced glulams except when unreinforced compression zone is stressed in tension (see Article C8.4.1.3.5). For tension-reinforced glulam beams where unreinforced compression zone is stressed in tension the volume factor, C_v , the same as for conventional glulam, shall be used.

8.4.4.6—Flat-Use Factor, C_{fu}

When dimension lumber graded as Structural Light Framing or Structural Joists and Planks is used flatwise (load applied to the wide face), the bending reference design value shall be multiplied by the flat use factor specified in Table 8.4.4.6-1. The flat-use factor shall not apply to dimension lumber graded as Decking.

Table 8.4.4.6-1—Flat-Use Factor, C_{fu} , for Dimension Lumber

Width (in.)	Thickness (in.)	
	2 and 3	4
2 and 3	1.00	—
4	1.10	1.00
5	1.10	1.05
6	1.15	1.05
8	1.15	1.05
≥ 10	1.20	1.10

Reference design values for flexure of vertically laminated glulam (loads applied parallel to wide faces of laminations) shall be multiplied by the flat use factors specified in Table 8.4.4.6-2 when the member dimension parallel to wide faces of laminations is less than 12.0 in.

C8.4.4.6

Design values for flexure of dimension lumber adjusted by the size factor, C_F , are based on edgewise use (load applied to the narrow face). When dimension lumber is used flatwise (load applied to the wide face), the bending reference design value should also be multiplied by the flat use factor specified in Table 8.4.4.6-1.

Design values for dimension lumber graded as Decking are based on flatwise use. Further adjustment by the flat-use factor is not permitted.

Table 8.4.4.6-2—Flat-Use Factor, C_{fu} , for Glulam

Member Dimension Parallel to Wide Faces of Laminations (in.)	C_{fu}
10 ³ / ₄ or 10 ¹ / ₂	1.01
8 ³ / ₄ or 8 ¹ / ₂	1.04
6 ³ / ₄	1.07
5 ¹ / ₈ or 5	1.10
3 ¹ / ₈ or 3	1.16
2 ¹ / ₂ or 2 ¹ / ₈	1.19

8.4.4.7—Incising Factor, C_i

Reference design values for dimension lumber shall be multiplied by the incising factor specified in Table 8.4.4.7-1 when members are incised parallel to grain a maximum depth of 0.4 in., a maximum length of ³/₈ in., and a density of incisions up to 1,100/ft². Incising factors shall be determined by test or by calculation using reduced section properties for incising patterns exceeding these limits.

Table 8.4.4.7-1—Incising Factor, C_i , for Dimension Lumber

Design Value	C_i
E_o	0.95
F_{bo} , F_{to} , F_{co} , F_{vo}	0.80
F_{cpo}	1.00

8.4.4.8—Deck Factor, C_d

Unless specified otherwise in this Article, the deck factor, C_d , shall be equal to 1.0.

For stressed wood, nail-laminated, and spike-laminated decks constructed of solid sawn lumber 2.0 in. to 4.0 in. thick, F_{bo} may be adjusted by C_d as specified in Table 8.4.4.8-1.

Table 8.4.4.8-1—Deck Factor, C_d , for Stressed Wood and Laminated Decks

Deck Type	Lumber Grade	C_d
Stressed Wood	Select Structural	1.30
	No. 1 or No. 2	1.50
Spike-Laminated or Nail-Laminated	All	1.15

C8.4.4.8

Mechanically laminated decks made of stressed wood, spike-laminated, or nail-laminated solid sawn lumber exhibit an increased resistance in bending. The resistance of mechanically laminated solid sawn lumber decks is calculated by multiplying F_{bo} in Table 8.4.1.1.4-1 by the deck factor.

Deck factor is used instead of the repetitive member factor that is used in NDS®.

For planks 4×6 in., 4×8 in., 4×10 in., and 4×12 in., used in plank decks with the load applied to the wide face of planks, F_{bo} may be adjusted by C_d as specified in Table 8.4.4.8-2.

Table 8.4.4.8-2—Deck Factor, C_d , for Plank Decks

Size (in.)	C_d
4×6	1.10
4×8	1.15
4×10	1.25
4×12	1.50

The deck factors for planks in plank decks shall not be applied cumulatively with the flat use factor, C_{fu} , specified in Article 8.4.4.6.

8.4.4.9—Time Effect Factor, C_λ

The time effect factor, C_λ shall be chosen to correspond to the appropriate strength limit state as specified in Table 8.4.4.9-1.

Table 8.4.4.9-1—Time Effect Factor, C_λ

Limit State	C_λ
Strength I	0.8
Strength II	1.0
Strength III	1.0
Strength IV	0.6
Extreme Event I	1.0

8.5—LIMIT STATES

8.5.1—Service Limit State

The provisions of Article 2.5.2.6.2 should be considered.

8.5.2—Strength Limit State

8.5.2.1—General

Factored resistance shall be the product of nominal resistance determined in accordance with Articles 8.6, 8.7, 8.8, and 8.9 and the resistance factor as specified in Article 8.5.2.2.

8.5.2.2—Resistance Factors

Resistance factors, ϕ , shall be as given below:

Flexure $\phi = 0.85$
 Shear $\phi = 0.75$

The specified deck factors for planks in plank decks are based test results comparing the modulus of rupture (MOR) for plank specimens with load applied in narrow face and wide face (*Stankiewicz and Nowak, 1997*). These deck factors can be applied cumulatively with the size factor, C_F , specified in Article 8.4.4.4.

C8.4.4.9

NDS® and ANSI 117 reference design values (based on 10-year loading) multiplied by the format conversion factors specified in Article 8.4.4.2, transform allowable stress values to strength level stress values based on 10-min. loading. It is assumed that a cumulative duration of bridge live load is 2 months and the corresponding time effect factor for Strength I is 0.8. A cumulative duration of live load in Strength II is shorter and the corresponding time effect factor for Strength II is 1.0. Resistance of wood subjected to long-duration loads is reduced. Load combination IV consists of permanent loads, including dead load and earth pressure.

C8.5.2.2

In the case of timber pile foundations, the resistance factor may be raised to 1.0 when, in the judgment of the Engineer, a sufficient number of piles is used in a foundation element to consider it to be highly redundant.

Compression Parallel to Grain	$\phi = 0.90$
Compression Perpendicular to Grain	$\phi = 0.90$
Tension Parallel to Grain	$\phi = 0.80$
Resistance During Pile Driving.....	$\phi = 1.15$
Connections	$\phi = 0.65$

This is indicated to be a judgment issue because there are no generally accepted quantitative guidelines at this writing.

For timber piles, the resistance factor to be applied when determining the maximum allowable driving resistance accounts for the short duration of the load induced by the pile driving hammer.

8.5.2.3—Stability

The structure as a whole or its components shall be proportioned to resist sliding, overturning, uplift, and buckling.

8.5.3—Extreme Event Limit State

For extreme event limit state, the resistance factor shall be taken as 1.0.

8.6—COMPONENTS IN FLEXURE

8.6.1—General

The factored resistance, M_r , shall be taken as:

$$M_r = \phi M_n \quad (8.6.1-1)$$

where:

$$M_n = \text{nominal resistance specified herein (kip-in.)}$$

ϕ = resistance factor specified in Article 8.5.2

8.6.2—Rectangular Section

The nominal resistance, M_n , of a rectangular component in flexure shall be determined from:

$$M_a = F_b SC_L \quad (8.6.2-1)$$

in which:

$$C_L = \frac{1+A}{1.9} - \sqrt{\frac{(1+A)^2}{3.61} - \frac{A}{0.95}} \quad (8.6.2-2)$$

$$A = \frac{F_{bE}}{F_b} \quad (8.6.2-3)$$

$$F_{bE} = \frac{K_{bE} E}{R_b^2} \quad (8.6.2-4)$$

$$R_b = \sqrt{\frac{L_e d}{b^2}} \leq 50 \quad (8.6.2-5)$$

where:

C8.6.2

If lateral support is provided to prevent rotation at the points of bearing, but no other lateral support is provided throughout the bending component length, the unsupported length, L_{ur} , is the distance between such points of intermediate lateral support.

The volume factor for the tension-reinforced glulams listed in Table 8.4.1.3.4-1 is equal to 1; therefore, for these beams, C_L will always be less than or equal to C_V , and C_L will control the modification factor for the allowable bending strength, F_b .

The factored shear resistance, V_r , of a component of rectangular cross section shall be calculated from:

$$V_r = \phi V_n \quad (8.7-1)$$

in which:

$$V_n = \frac{F_v b d}{1.5} \quad (8.7-2)$$

where:

ϕ = resistance factor specified in Article 8.5.2.2
 F_v = adjusted design value of wood in shear, specified in Article 8.4.4.1 (ksi)

Note that Eq. 4.6.2.2.2a-1 requires a special distribution factor in the calculation of the live load force effect when investigating shear parallel to the grain.

8.8—COMPONENTS IN COMPRESSION

8.8.1—General

The factored resistance in compression, P_r , shall be taken as:

$$P_r = \phi P_n \quad (8.8.1-1)$$

where:

ϕ = resistance factor specified in Article 8.5.2.2
 P_n = nominal resistance as specified in Articles 8.8.2 and 8.8.3 (kips)

8.8.2—Compression Parallel to Grain

Where components are not adequately braced, the nominal stress shall be modified by the column stability factor, C_p . If the component is adequately braced, C_p shall be taken as 1.0.

The nominal resistance, P_n , of a component in the compression parallel to grain shall be taken as:

$$P_n = F_c A_g C_p \quad (8.8.2-1)$$

in which:

$$C_p = \frac{1+B}{2c} - \sqrt{\left(\frac{1+B}{2c}\right)^2 - \frac{B}{c}} \leq 1.0 \quad (8.8.2-2)$$

$$B = \frac{F_{cE}}{F_c} \leq 1.0 \quad (8.8.2-3)$$

$$F_{cE} = \frac{K_{cE} E d^2}{L_e^2} \quad (8.8.2-4)$$

where:

A_g = gross cross-sectional area of the component (in.²)

C8.8.2

The coefficient of variation of the bending modulus of rupture (*MOR*) of tension-reinforced glulams has been shown through extensive testing to be less than or equal to that of conventional unreinforced glulams. Therefore, it is conservative to use $K_{cE} = 0.76$ for tension-reinforced glulams.

F_t = adjusted design value of wood in tension specified in Article 8.4.4.1 (ksi)

A_n = smallest net cross-sectional area of the component (in.²)

8.10—COMPONENTS IN COMBINED FLEXURE AND AXIAL LOADING

8.10.1—Components in Combined Flexure and Tension

C8.10.1

Components subjected to flexure and tension shall satisfy:

$$\frac{P_u}{P_r} + \frac{M_u}{M_r} \leq 1.0 \quad (8.10.1-1)$$

and

$$\frac{M_v - \frac{d}{6} P_v}{M_v^{**}} \leq 1.0 \quad (8.10.1-2)$$

where:

$$P_u = \text{factored tensile load (kips)}$$

P_r = factored tensile resistance calculated as specified in Article 8.9 (kips)

$$M_u = \text{factored flexural moment (kip-in.)}$$
$$M_r^* = F_b S$$

M_r^{**} = factored flexural resistance adjusted by all applicable adjustment factors except C_V

Satisfying Eq. 8.10.1-1 ensures that stress interaction on the tension face of the bending member does not cause beam rupture. M_r^* in this formula does not include modification by the beam stability factor, C_L .

Eq. 8.10.1-2 is applied to ensure that the bending/tension member does not fail due to lateral buckling of the compression face.

8.10.2—Components in Combined Flexure and Compression Parallel to Grain

Components subjected to flexure and compression parallel to grain shall satisfy:

$$\left(\frac{P_u}{P_r}\right)^2 + \frac{M_u}{M_r \left(1 - \frac{P_u}{F_x A_o}\right)} \leq 1.0 \quad (8.10.2-1)$$

where:

$$P_u = \text{factored compression load (kips)}$$

P_r = factored compressive resistance calculated as specified in Article 8.8 (kips)

 M_u = factored flexural moment (kip-in.)

M_r = factored flexural resistance calculated as specified in Article 8.6 (kip-in.)

F_{CE} = Euler buckling stress as defined in Eq. 8.8.2-4

A_g = gross cross-sectional area (in.²)

8.11—BRACING REQUIREMENTS

8.11.1—General

Where bracing is required, it shall prevent both lateral and rotational deformation.

8.11.2—Sawn Wood Beams

Beams shall be transversely braced to prevent lateral displacement and rotation of the beams and to transmit lateral forces to the bearings. Transverse bracing shall be provided at the supports for all span lengths and at intermediate locations for spans longer than 20.0 ft. The spacing of intermediate bracing shall be based on lateral stability and load transfer requirements but shall not exceed 25.0 ft. The depth of transverse bracing shall not be less than three fourths the depth of the stringers or girders.

Transverse bracing should consist of solid wood blocking or fabricated steel shapes. Wood blocking shall be bolted to stringers with steel angles or suspended in steel saddles that are nailed to the blocks and stringer sides. Blocking shall be positively connected to the beams.

Transverse bracing at supports may be placed within a distance from the center of bearing equal to the stringer or girder depth.

8.11.3—Glued Laminated Timber Girders

Transverse bracing should consist of fabricated steel shapes or solid wood diaphragms.

Girders shall be attached to supports with steel shoes or angles that are bolted through the girder and into or through the support.

8.11.4—Bracing of Trusses

Wood trusses shall be provided with a rigid system of lateral bracing in the plane of the loaded chord. Lateral bracing in the plane of the unloaded chord and rigid portal and sway bracing shall be provided in all trusses having sufficient headroom. Outrigger bracing connected to extensions of the floorbeams shall be used for bracing through-trusses having insufficient headroom for a top chord lateral bracing system.

8.12—CAMBER REQUIREMENTS

8.12.1—Glued Laminated Timber Girders

Glued laminated timber girders shall be cambered a minimum of two times the dead load deflection at the service limit state.

C8.11.1

In detailing of the diaphragms, the potential for shrinkage and expansion of the beam and the diaphragm should be considered. Rigidly connected steel angle framing may cause splitting of the beam and diaphragm as the wood attempts to swell and shrink under the effects of cyclic moisture.

C8.11.2

The effectiveness of the transverse bracing directly affects the long-term durability of the system. The bracing facilitates erection, improves load distribution, and reduces relative movements of the stringers and girders, thereby reducing deck deformations. Excessive deformation can lead to mechanical deterioration of the system.

Bracing should be accurately framed to provide full bearing against stringer sides. Wood cross-frames or blocking that are toe-nailed to stringers have been found to be ineffective and should not be used.

C8.11.3

Bracing should be placed tight against the girders and perpendicular to the longitudinal girder axis.

C8.11.4

Bracing is used to provide resistance to lateral forces, to hold the trusses plumb and true, and to hold compression elements in line.

C8.12.1

The initial camber offsets the effects of dead load deflection and long-term creep deflection.

8.12.2—Trusses

Trusses shall be cambered to sufficiently offset the deflection due to dead load, shrinkage, and creep.

C8.12.2

Camber should be determined by considering both elastic deformations due to applied loads and inelastic deformations such as those caused by joint slippage, creep of the timber components, or shrinkage due to moisture changes in the wood components.

8.12.3—Stress Laminated Timber Deck Bridge

Deck bridges shall be cambered for three times the dead load deflection at the service limit state.

8.13—CONNECTION DESIGN

The design of timber connections using mechanical fasteners including, wood screws, nails, bolts, lag screws, drift bolts, drift pins, shear plates, split rings, and timber rivets shall be in accordance with the 2018 *NDS*[®].

SECTION 9

DECKS AND DECK SYSTEMS

Commentary is opposite the text it annotates.

9.1—SCOPE

This Section contains provisions for the analysis and design of bridge decks and deck systems of concrete, metal, wood, or combinations thereof subjected to gravity loads.

For monolithic concrete bridge decks satisfying specific conditions, an empirical design, requiring no analysis, is permitted.

Continuity in the deck and its supporting components is encouraged.

Composite action between the deck and its supporting components is required where technically feasible.

C9.1

Implicit in this Section is a design philosophy that prefers jointless, continuous bridge decks and deck systems to improve the weather- and corrosion-resisting effects of the whole bridge, reduce inspection efforts and maintenance costs, and increase structural effectiveness and redundancy.

9.2—DEFINITIONS

Appurtenances—Curbs, parapets, railings, barriers, dividers, and sign and lighting posts attached to the deck.

Arching Action—A structural phenomenon in which wheel loads are transmitted primarily by compressive struts formed in the slab.

Band—A strip of laminated wood deck within which the pattern of butt joints is not repeated.

Bolster—A spacer between a metal deck and a beam.

Bulkhead—A steel element attached to the side of stress-laminated timber decks to distribute the prestressing force and reduce the tendency to crush the wood.

Cellular Deck—A concrete deck with void-ratio in excess of 40 percent.

Clear Span—The face-to-face distance between supporting components.

Closed Rib—A rib in an orthotropic deck consisting of a plate forming a trough, welded to the deck plate along both sides of the rib.

Closure Joint—A cast-in-place concrete fill between precast components to provide continuity.

Compatibility—The equality of deformation at the interface of elements, components, or both joined together.

Component—A structural element or combination of elements requiring individual design consideration.

Composite Action—A condition in which two or more elements or components are made to act together by preventing relative movement at their interface.

Continuity—In decks, both structural continuity and the ability to prevent water penetration without the assistance of nonstructural elements.

Core Depth—The distance between the top of top reinforcement and the bottom of bottom reinforcement in a concrete slab.

Deck—A component, with or without wearing surface, that supports wheel loads directly and is supported by other components.

Deck Joint—A complete or partial interruption of the deck to accommodate relative movement between portions of a structure.

Deck System—A superstructure, in which the deck is integral with its supporting components, or in which the effects or deformation of supporting components on the behavior of the deck is significant.

Design Span—For decks, the center-to-center distance between the adjacent supporting components, taken in the primary direction.

Effective Length—The span length used in the empirical design of concrete slabs defined in Article 9.7.2.3.

Elastic—A structural response in which stress is directly proportional to strain and no deformation remains upon removal of loading.

Equilibrium—A state where the sum of forces parallel to any axis and the sum of moments about any axis in space are 0.0.

Equivalent Strip—An artificial linear element, isolated from a deck for the purpose of analysis, in which extreme force effects calculated for a line of wheel loads, transverse or longitudinal, will approximate those actually taking place in the deck.

Extreme—Maximum or minimum.

Flexural Continuity—The ability to transmit moment and rotation between components or within a component.

Floorbeam—The traditional name for a cross-beam.

Footprint—The specified contact area between wheel and roadway surface.

Frame Action—Transverse continuity between the deck and the webs of cellular cross-section or between the deck and primary components in large bridges.

Glued Laminated Deck Panel—A deck panel made from wood laminations connected by adhesives.

Governing Position—The location and orientation of a transient load to cause extreme force effects.

Inelastic—The structural response in which stress is not directly proportional to strain and deformation may remain upon removal of loading.

Interface—The location where two elements and/or components are in contact.

Internal Composite Action—The interaction between a deck and a structural overlay.

Isotropic Plate—A plate having essentially identical structural properties in the two principal directions.

Isotropic Reinforcement—Two identical layers of reinforcement, perpendicular to and in touch with each other.

Lateral—Any horizontal or close to horizontal direction.

Laminated Deck—A deck consisting of a series of laminated wood elements that are tightly abutted along their edges to form a continuous surface.

Local Analysis—An in-depth study of strains and stresses in or among components using force effects obtained from global analysis.

Net Depth—The depth of concrete, excluding the concrete placed in the corrugations of a metal formwork.

Open Grid Floor—A metal grid floor not filled or covered with concrete.

Open Rib—A rib in an orthotropic deck consisting of a single plate or rolled section welded to the deck plate.

Orthotropic—A plate having significantly different structural properties in the two principal directions.

Overfill—The concrete above the top of the steel grid of filled or partially filled steel grid deck systems.

Partial Composite Action—A condition in which two or more elements or components are made to act together by decreasing, but not eliminating, relative movement at their interface, or where the connecting elements are too flexible to fully develop the deck in composite action.

Primary Direction—In isotropic decks: direction of the shorter span; in orthotropic decks: direction of the main load-carrying elements.

Secondary Direction—The direction normal to the primary direction.

Segmental Construction—A method of building a bridge utilizing match-cast, prefabricated, or cast-in-place concrete segments joined together by longitudinal post-tensioning.

Shear Connector—A mechanical device that prevents relative movements both normal and parallel to an interface.

Shear Continuity—A condition where shear and displacement are transmitted between components or within a component.

Shear Key—A preformed hollow in the side of a precast component filled with grout or a system of match-cast depressions and protrusions in the face of segments that is intended to provide shear continuity between components.

Skew Angle—The angle between the axis of support relative to a line normal to the longitudinal axis of the bridge; e.g., a zero-degree skew denotes a rectangular bridge.

Spacing—Center-to-center distance of elements or components, such as reinforcing bars, girders, bearings, etc.

Stay-in-Place Formwork—Permanent metal or precast concrete forms that remain in place after construction is finished.

Stiffener Beam—An unsupported beam attached to the underside of a wood deck to enhance lateral continuity.

Stress Range—The algebraic difference between extreme stresses.

Structural Overlay—An overlay bonded to the deck that consists of concretes other than asphaltic concretes.

Tandem—Two closely spaced and mechanically interconnected axles of equal weight.

Tie-Down—A mechanical device that prevents relative movement normal to an interface.

Void—An internal discontinuity of the deck by which its self-weight is reduced.

Voided Deck—Concrete deck in which the area of the voids does not constitute more than 40 percent of the gross area.

Wearing Surface—An overlay or sacrificial layer of the structural deck to protect the structural deck against wear, road salts, and environmental effects. The overlay may include waterproofing.

Wheel—One tire or a pair of tires at one end of an axle.

Wheel Load—One-half of a specified design axle load.

Yield Line—A plastic hinge line.

Yield Line Analysis—A method of determining the load-carrying capacity of a component on the basis of the formation of a mechanism.

Yield Line Method—A method of analysis in which a number of possible yield line patterns of concrete slabs are examined in order to determine minimum load-carrying capacity.

9.3—NOTATION

A_B	=	effective bearing area of anchorage bulkhead (in. ²) (9.9.5.6.3)
A_s	=	area of steel bar or strand (in. ²) (9.9.5.6.3)
c	=	depth of the bottom cutout to accommodate a rib in an orthotropic deck (in.) (C9.8.3.6.4)
d	=	effective depth: distance between the outside compressive fiber and the center of gravity of the tensile reinforcement (in.) (C9.7.2.5)
F	=	nominal bearing resistance of wood across the grain (ksi) (9.9.5.6.3)
$f_{0.5}$	=	the surface stress at a distance of 0.5 t from the weld toe (ksi) (9.8.3.4.4)
$f_{1.5}$	=	the surface stress at a distance of 1.5 t from the weld toe (ksi) (9.8.3.4.4)
h	=	depth of deck (in.) (9.9.5.6.3)
L	=	span length from center-to-center of supports (9.5.2)
P_{BU}	=	factored compressive resistance of the wood under the bulkhead (kip) (9.9.5.6.3)
P_{pt}	=	prestressing force per prestressing element (kip) (9.9.5.6.3)
R_{sw}	=	steel-wood ratio (9.9.5.6.3)
S	=	effective span length (ft) (9.7.3.2)
s	=	spacing of prestressing elements (in.) (9.9.5.6.3)
ϕ	=	resistance factor (9.9.5.6.3)

9.4—GENERAL DESIGN REQUIREMENTS

9.4.1—Interface Action

Decks other than wood and open grid floors shall be made composite with their supporting components, unless there are compelling reasons to the contrary. Noncomposite decks shall be connected to their supporting components to prevent vertical separation.

Shear connectors and other connections between decks, other than open grid floors and wood decks, and their supporting members shall be designed for force effects calculated on the basis of full composite action, whether or not that composite action is considered in proportioning the primary members. The details for transmitting shear across the interface to metal supporting components shall satisfy the applicable provisions of Article 6.6 or Article 7.6.

Force effects between the deck and appurtenances or other components shall be accommodated.

9.4.2—Deck Drainage

With the exception of unfilled steel grid decks, cross and longitudinal slopes of the deck surface shall be provided as specified in Article 2.6.6.

Structural effects of drainage openings shall be considered in the design of decks.

C9.4.1

Composite action is recommended to enhance the stiffness and economy of structures.

Some decks without shear connectors have historically demonstrated a degree of composite action due to chemical bond, friction, or a combination of both that cannot be accounted for in structural design.

It is difficult to design and detail a tie-down device that does not attract shear forces due to transient loads, temperature changes, and fluctuation in moisture content. These forces may loosen or break such devices, and cause fatigue damage in other parts of the floor system and its connections to main members, and to floorbeams in particular.

9.4.3—Concrete Appurtenances

Unless otherwise specified by the Owner, concrete curbs, parapets, barriers, and dividers should be made structurally continuous. Consideration of their structural contribution to the deck should be limited in accordance with the provisions of Article 9.5.1.

9.4.4—Edge Supports

Unless the deck is designed to support wheel loads in extreme positions with respect to its edges, edge supports shall be provided. Nonintegral edge beams shall conform to the provisions of Article 9.7.1.4.

9.4.5—Stay-in-Place Formwork for Overhangs

Stay-in-place formwork, other than that in filled steel decks, shall not be used in the overhang of concrete decks.

9.5—LIMIT STATES**9.5.1—General**

The structural contribution of a concrete appurtenance to the deck may be considered for service and fatigue but not for strength or extreme event limit states.

For other than the deck overhang, where the conditions specified in Article 9.7.2 are met, a concrete deck may be assumed to satisfy service, fatigue, and fracture and strength limit state requirements and need not meet the other provisions of Article 9.5.

9.5.2—Service Limit States

At service limit states, decks and deck systems shall be analyzed as fully elastic structures and shall be designed and detailed to satisfy the provisions of Sections 5, 6, 7, and 8.

The effects of excessive deck deformation, including deflection, shall be considered for metal grid decks and other lightweight metal and concrete bridge decks. For these deck systems, the deflection caused by live load plus dynamic load allowance shall not exceed the following criteria:

- $L/800$ for decks with no pedestrian traffic,
- $L/1,000$ for decks with limited pedestrian traffic, and
- $L/1,200$ for decks with significant pedestrian traffic

where:

L = span length from center-to-center of supports.

C9.4.3

Experience indicates that the interruption of concrete appurtenances at locations other than deck joints does not serve the intended purpose of stress relief. Large cracks, approximately 1 ft away from open joints, have been observed in concrete parapets. The structural participation of these components is usually, but not always, beneficial. One possible negative aspect of continuity is increased cracking in the appurtenance.

C9.4.4

If the deck joint hardware is integrated with the deck, it may be utilized as a structural element of the edge beam.

C9.5.1

Exclusion of contribution of an appurtenance at strength limit state is a safety measure in that advantage is not taken of a component that may be damaged, disconnected, or destroyed by a collision.

Article 9.7.2.2 states that the empirical design method does not apply to overhangs.

C9.5.2

Deck deformation refers to local dishing at wheel loads, not to overall superstructure deformation.

The primary objective of curtailing excessive deck deformation is to prevent breakup and loss of the wearing surface. No overall limit can be specified because such limit is a function of the composition of the wearing surface and the adhesion between the deck and the wearing surface. The limits should be established by testing.

Substantial work has been done relating accelerations to user comfort. Acceleration is a function of the fundamental frequency of vibration of the deck on a particular span, and the magnitude of dynamic deflection due to live load. Dynamic deflections are typically 15 percent to 20 percent of static deflections. Analysis shows that static deflections serve well as a proxy for acceleration levels for deck systems.

9.5.3—Fatigue and Fracture Limit State

Fatigue need not be investigated for:

- concrete decks and
- wood decks as listed in Article 9.9.

Open grid, filled grid, partially filled grid, and unfilled grid decks composite with reinforced concrete slabs shall comply with the provisions of Articles 4.6.2.1, 6.5.3, and 9.8.2.

Steel orthotropic decks shall comply with the provisions of Article 6.5.3. Aluminum decks shall comply with the provisions of Article 7.6.

Concrete decks, other than those in multigirder applications, shall be investigated for the fatigue limit states as specified in Article 5.5.3.

9.5.4—Strength Limit States

At strength limit states, decks and deck systems may be analyzed as either elastic or inelastic structures and shall be designed and detailed to satisfy the provisions of Sections 5, 6, 7, and 8.

9.5.5—Extreme Event Limit States

Decks shall be designed for force effects transmitted by traffic and combination railings using loads, analysis procedures, and limit states specified in Section 13. Acceptance testing complying with Section 13 may be used to satisfy this requirement.

9.6—ANALYSIS**9.6.1—Methods of Analysis**

Approximate elastic methods of analysis specified in Article 4.6.2.1, refined methods specified in Article 4.6.3.2, or the empirical design of concrete slabs specified in Article 9.7 may be used for various limit states as permitted in Article 9.5.

9.6.2—Loading

Loads, load positions, tire contact area, and load combinations shall be in accordance with the provisions of Section 3.

C9.5.3

The provisions that do not require fatigue investigation of certain types of decks are based exclusively on observed performance and laboratory testing.

A series of 35 pulsating load fatigue tests of model slabs indicate that the fatigue limit for the slabs designed by the conventional AASHTO moment methods was approximately three times the service level. Decks based on the isotropic reinforcement method specified in Article 9.7.2 had fatigue limits of approximately twice the service level (deV Batchelor et al., 1978).

C9.5.4

These Specifications do not permit an unlimited application of inelastic methods of analysis due to the lack of adequate background research. There are, however, well-established inelastic plate analyses whose use is allowed.

C9.6.1

Analytical methods presented herein should not be construed as excluding other analytical approaches, provided that they are approved by the Owner.

9.7—CONCRETE DECK SLABS**9.7.1—General****9.7.1.1—Minimum Depth and Cover**

Unless approved by the Owner, the depth of a concrete deck, excluding any provision for grinding, grooving, and sacrificial surface, should not be less than 7.0 in.

Minimum cover shall be in accordance with the provisions of Article 5.10.1.

9.7.1.2—Composite Action

Shear connectors shall be designed in accordance with the provisions of Section 5 for concrete beams and Sections 6 and 7 for metal beams.

9.7.1.3—Skewed Decks

If the skew angle of the deck does not exceed 25 degrees, the primary reinforcement may be placed in the direction of the skew; otherwise, it shall be placed perpendicular to the main supporting components.

C9.7.1.1

For slabs of depth less than $1/20$ of the design span, consideration should be given to prestressing in the direction of that span in order to control cracking.

Construction tolerances become a concern for thin decks.

Minimum cover requirements are based on traditional concrete mixes and on the absence of protective coating on either the concrete or the steel inside. A combination of special mix design, protective coatings, dry or moderate climate, and the absence of corrosion chemicals may justify a reduction of these requirements provided that the Owner approves.

C9.7.1.2

Some research efforts have dealt with wood beams composite with concrete decks and steel beams with stressed wood decks, but progress is not advanced to a point which permits codification.

C9.7.1.3

The intent of this provision is to prevent extensive cracking of the deck, which may result from the absence of appreciable reinforcement acting in the direction of principal flexural stresses due to a heavily skewed reinforcement, as shown in Figure C9.7.1.3-1. The somewhat arbitrary 25-degree limit could affect the area of steel as much as ten percent. This was not taken into account because the analysis procedure and the use of bending moment as a basis of design were not believed to be sufficiently accurate to warrant such an adjustment. Owners interested in making this refinement should also consider one of the refined methods of analysis identified in Article 4.6.3.2.

Figure C9.7.1.3-1—Reinforcement Layout

9.7.1.4—Edge Support

Unless otherwise specified, at lines of discontinuity, the edge of the deck shall either be strengthened or be supported by a beam or other line component. The beam or component shall be integrated in or made composite with the deck. The edge beams may be designed as beams whose width may be taken as the effective width of the deck specified in Article 4.6.2.1.4.

Where the primary direction of the deck is transverse, and/or the deck is composite with a structurally continuous concrete barrier, no additional edge beam need be provided.

9.7.1.5—Design of Cantilever Slabs

The overhanging portion of the deck shall be designed for railing impact loads and in accordance with the provisions of Article 3.6.1.3.4.

Punching shear effects at the outside toe of a railing post or barrier due to vehicle collision loads shall be investigated.

9.7.1.6—Minimum Deck Reinforcement in Negative Moment Region

Wherever the longitudinal tensile stress in the concrete deck due to either the factored construction loads or Load Combination Service I in Table 3.4.1-1 exceeds Φf_r , the total cross-sectional area of the longitudinal reinforcement shall not be less than one percent of the total cross-sectional area of the concrete deck. When partial depth precast deck panels are used as deck forms, the total cross-sectional area of the longitudinal reinforcement shall not be less than one percent of the total cross-sectional area of the cast-in-place deck portion only. Φ shall be taken as 0.9 and f_r shall be taken as the modulus of rupture of the concrete determined as specified in Article 5.4.2.6.

9.7.2—Empirical Design

9.7.2.1—General

The provisions of Article 9.7.2 relate exclusively to the empirical design process for concrete deck slabs supported by longitudinal components and shall not be applied to any other Article in this Section, unless specifically permitted.

C9.7.1.5

An acceptable method of analyzing deck overhangs for railing impact loads is presented in the Appendix to Section 13.

Any combination of increasing the depth of the slab, employing special reinforcement extending the slab width beyond the railing, and enlarging base plates under railing posts may be utilized to prevent failure due to punching shear.

C9.7.1.6

The use of one percent reinforcement with a size not exceeding No. 6 bars, a yield strength greater than or equal to 60 ksi and spacing at intervals not exceeding 12 in. has been shown to control concrete cracking (Ge et al., 2021). Using these requirements is expected to limit crack widths to 0.012 in. If smaller crack widths are desired, the spacing can be designed based on the restraint moment due to the concrete shrinkage and the live load as shown in Ge et al. (2021).

C9.7.2.1

Extensive research into the behavior of concrete deck slabs discovered that the primary structural action by which these slabs resist concentrated wheel loads is not flexure, as traditionally believed, but a complex internal membrane stress state referred to as internal arching. This action is made possible by the cracking of the concrete in the positive moment region of the design slab and the resulting upward shift of the neutral axis in that portion of the slab. The action is sustained by in-plane membrane forces that develop as a result of lateral confinement provided by the surrounding concrete slab, rigid appurtenances, and supporting components acting compositely with the slab.

The longitudinal bars of the isotropic reinforcement may participate in resisting negative moments at an internal support in continuous structures.

9.7.2.2—Application

Empirical design of reinforced concrete decks may be used if the conditions set forth in Article 9.7.2.4 are satisfied.

The provisions of this Article shall not be applied to overhangs.

The overhang should be designed for:

- wheel loads for decks with discontinuous railings and barriers using the equivalent strip method,
- equivalent line load for decks with continuous barriers specified in Article 3.6.1.3.4, and
- collision loads using a failure mechanism as specified in Article A13.2.

The arching creates what can best be described as an internal compressive dome, the failure of which usually occurs as a result of overstraining around the perimeter of the wheel footprint. The resulting failure mode is that of punching shear, although the inclination of the fracture surface is much less than 45 degrees due to the presence of large in-plane compressive forces associated with arching. The arching action, however, cannot resist the full wheel load. There remains a small flexural component for which the specified minimum amount of isotropic reinforcement is more than adequate. The steel has a dual purpose: it provides for both local flexural resistance and global confinement required to develop arching effects (Fang, 1985) (Holowka et al., 1980).

All available test data indicate that the factor of safety of a deck designed by the flexural method specified in the 17th edition of the AASHTO *Standard Specifications for Highway Bridges* (2002), working stress design, is at least 10.0. Tests indicate a comparable factor of safety of about 8.0 for an empirical design. Therefore, even the empirical design possesses an extraordinary reserve strength.

The design of reinforced concrete decks using the concept of internal arching action within the limits specified herein has been verified by extensive nonlinear finite element analysis (Hewitt and deV Batchelor, 1975) (Fang et al. 1990). These analyses are accepted in lieu of project-specific design calculations as a preapproved basis of design.

Slabs with the minimum specified reinforcement have demonstrated nearly complete insensitivity to differential displacement among their supports.

The additional longitudinal reinforcement provided for the slab in the negative moment region of continuous beams and girder-type bridges beyond that required for isotropic reinforcement according to the provisions of Article 9.7.2.5 need not be matched in the perpendicular direction. Theoretically, this portion of the deck will be orthotropically reinforced, but this does not weaken the deck.

C9.7.2.2

Although testing has indicated that arching action may exist in the cantilevered overhang of the slab, the available evidence is not sufficient to formulate code provisions for it (Hays et al., 1989).

As indicated in Article 9.5.5, acceptance testing complying with Section 13 may be used to satisfy design requirements for deck overhangs.

9.7.2.3—Effective Length

For the purpose of the empirical design method, the effective length of slab shall be taken as:

- **For slabs monolithic with walls or beams:** the face-to-face distance, and
- **For slabs supported on steel or concrete girders:** the distance between flange tips, plus the flange overhang, taken as the distance from the extreme flange tip to the face of the web, disregarding any fillets.

In case of nonuniform spacing of supporting components, the effective length, $S_{\text{effective}}$, shall be taken as the larger of the deck lengths at the two locations shown in Figure 9.7.2.3-1.

Figure 9.7.2.3-1—Effective Length for Nonuniform Spacing of Beams

9.7.2.4—Design Conditions

For the purpose of this Article, the design depth of the slab shall exclude the loss that is expected to occur as a result of grinding, grooving, or wear. The empirical design may be used only if the following conditions are satisfied:

- Cross-frames or diaphragms are used throughout the cross-section at lines of support;
- For cross-sections involving torsionally stiff units, such as individual separated box beams, either intermediate diaphragms between the boxes are provided at a spacing not to exceed 25.0 ft, or the need for supplemental reinforcement over the webs to accommodate transverse bending between the box units is investigated and reinforcement is provided if necessary;

C9.7.2.3

Physical tests and analytical investigations indicate that the most important parameter concerning the resistance of concrete slabs to wheel loads is the ratio between the effective length and the depth of the slab.

C9.7.2.4

Intermediate cross-frames are not needed in order to use the empirical deck design method for cross-sections involving torsionally weak open shapes, such as T- or I-shaped girders.

Use of separated, torsionally stiff beams without intermediate diaphragms can give rise to the situation, shown in Figure C9.7.2.4-1, in which there is a relative displacement between beams and in which the beams do not rotate sufficiently to relieve the moment over the webs. This moment may or may not require more reinforcing than is provided by the empirical deck design.

- The supporting components are made of steel and/or concrete;
- The deck is fully cast-in-place and water cured;
- The deck is of uniform depth, except for haunches at girder flanges and other local thickening;
- The ratio of effective length to design depth does not exceed 18.0 and is not less than 6.0;
- Core depth of the slab is not less than 4.0 in.;
- The effective length, as specified in Article 9.7.2.3, does not exceed 13.5 ft;
- The minimum depth of the slab is not less than 7.0 in., excluding a sacrificial wearing surface where applicable;

Figure C9.7.2.4-1—Schematic of Effect of Relative Displacements in Torsionally Stiff Cross-Section

All the tests carried out so far were restricted to specimens of uniform depth. Slabs supported by wood beams are not qualified for the empirical design due to the lack of experimental evidence regarding adequate lateral shear transfer between the slab and the relatively soft timber beams.

No experience exists for effective lengths exceeding 13.5 ft. The 7.0-in. depth is considered an absolute minimum with 2.0-in. cover on top and 1.0-in. cover on the bottom, providing for a reinforced core of 4.0 in., as indicated in Figure C9.7.2.4-2.

Figure C9.7.2.4-2—Core of a Concrete Slab

The provisions of the *Ontario Highway Bridge Design Code* (OHBDC, 1991), based on model test results, do not permit length-to-depth ratios in excess of 15.0. The larger value of 18.0 is based on Hays et al. (1989).

The intention of the overhang provision is to ensure confinement of the slab between the first and the second beam.

The 4.0-ksi limit is based on the fact that none of the tests included concrete with less than 4.0-ksi strength at 28 days. Many jurisdictions specify 4.5-ksi concrete for ensuring reduced permeability of the deck. On the other hand, tests indicate that resistance is not sensitive to the compressive strength, and 3.5 ksi may be accepted with the approval of the Owner.

- There is an overhang beyond the centerline of the outside girder of at least 5.0 times the depth of the slab; this condition is satisfied if the overhang is at least 3.0 times the depth of the slab and a structurally continuous concrete barrier is made composite with the overhang;
- The specified 28-day strength of the deck concrete is not less than 4.0 ksi; and
- The deck is made composite with the supporting structural components.

For the purpose of this Article, a minimum of two shear connectors at 24.0-in. centers shall be provided in the negative moment region of continuous steel superstructures. The provisions of Article 6.10.1.1 shall also be satisfied. For concrete girders, the use of stirrups extending into the deck shall be taken as sufficient to satisfy this requirement.

9.7.2.5—Reinforcement Requirements

Four layers of isotropic reinforcement shall be provided in empirically designed slabs. Reinforcement shall be located as close to the outside surfaces as permitted by cover requirements. Reinforcement shall be provided in each face of the slab with the outermost layers placed in the direction of the effective length. The minimum amount of reinforcement shall be 0.27 in.²/ft of steel for each bottom layer and 0.18 in.²/ft of steel for each top layer. Spacing of steel shall not exceed 18.0 in. Reinforcing steel shall be Grade 60 or better. All reinforcement shall be straight bars, except that hooks may be provided where required.

Both lap splices and mechanical splices shall be allowed. Mechanical splices shall be tested and approved to conform to the limits for slip in Article 5.10.8.4.2b and for fatigue in Article 5.5.3.4. Sleeve wedge-type couplers shall not be permitted on coated reinforcing.

If the skew exceeds 25 degrees, the specified reinforcement in both directions shall be doubled in the end zones of the deck. Each end zone shall be taken as a longitudinal distance equal to the effective length of the slab specified in Article 9.7.2.3.

9.7.2.6—Deck with Stay-in-Place Formwork

For decks made with corrugated metal formwork, the design depth of the slab shall be assumed to be the minimum concrete depth.

Stay-in-place concrete formwork shall not be permitted in conjunction with empirical design of concrete slabs.

9.7.3—Traditional Design**9.7.3.1—General**

The provisions of this Article shall apply to concrete slabs that have four layers of reinforcement, two in each direction, and that comply with Article 9.7.1.1.

C9.7.2.5

Prototype tests indicated that 0.2 percent reinforcement in each of four layers based on the effective depth, d , satisfies strength requirements. However, the conservative value of 0.3 percent of the gross area, which corresponds to about 0.27 in.²/ft in a 7.5-in. slab, is specified for better crack control in the positive moment area. Field measurements show very low stresses in negative moment steel; this is reflected by the 0.18-in.²/ft requirement, which is about 0.2 percent reinforcement steel. The additional intent of this low amount of steel is to prevent spalling of the deck due to corrosion of the bars or wires.

Welded splices are not permitted due to fatigue considerations. Tested and preapproved mechanical splices may be permitted when lapping of reinforcing is not possible or desirable, as often occurs in staged construction and widenings. Sleeve wedge-type couplers will not be permitted on coated reinforcing due to stripping of the coating.

The intent of this provision is crack control. Beam slab bridges with a skew exceeding 25 degrees have shown a tendency to develop torsional cracks due to differential deflections in the end zone (OHBD, 1991). The extent of cracking is usually limited to a width that approximates the effective length.

C9.7.2.6

Concrete in the troughs of the corrugated metal deck is ignored due to lack of evidence that it consistently contributes to the strength of the deck. Reinforcement should not be placed directly on corrugated metal formwork.

The empirical design is based on a radial confinement around the wheel load, which may be weakened by the inherent discontinuity of the bottom reinforcement at the boundaries between formwork panels. Limited tests carried out on flexurally designed slabs with stay-in-place concrete formwork indicate a punching shear failure mode, but somewhat less resistance than that provided by fully cast-in-place slabs. The reason for this decrease is that the discontinuity between the panels intercepts, and thus prevents, the undisturbed formation of the frustum of a cone where punching shear occurs (Buth et al., 1992).

C9.7.3.1

The traditional design is based on flexure. The live load force effect in the slab may be determined using the approximate methods of Article 4.6.2.1 or the refined methods of Article 4.6.3.2.

9.7.3.2—Distribution Reinforcement

Reinforcement shall be placed in the secondary direction in the bottom of slabs as a percentage of the primary reinforcement for positive moment as follows:

- For primary reinforcement parallel to traffic:

$$100/\sqrt{S} \leq 50 \text{ percent}$$

- For primary reinforcement perpendicular to traffic:

$$220/\sqrt{S} \leq 67 \text{ percent}$$

where:

S = the effective span length taken as equal to the effective length specified in Article 9.7.2.3 (ft)

9.7.4—Stay-in-Place Formwork

9.7.4.1—General

Stay-in-place formwork shall be designed to be elastic under construction loads. The construction load shall not be taken to be less than the weight of the form and the concrete slab plus 0.050 ksf.

Flexural stresses due to unfactored construction loads shall not exceed:

- 75 percent of the yield strength of steel, or
- 65 percent of the 28-day compressive strength for concrete in compression or the modulus of rupture in tension for prestressed concrete form panels.

The elastic deformation caused by the dead load of the forms, plastic concrete, and reinforcement shall not exceed:

- **For form span lengths of 10.0 ft or less:** the form span length divided by 180 but not exceeding 0.50 in.; or
- **For form span lengths greater than 10.0 ft:** the form span length divided by 240 but not exceeding 0.75 in.

9.7.4.2—Steel Formwork

Panels shall be specified to be tied together mechanically at their common edges and fastened to their support. No welding of the steel formwork to the supporting components shall be permitted, unless otherwise shown in the contract documents.

Steel formwork shall not be considered to be composite with a concrete slab.

C9.7.4.1

The intent of this Article is to prevent excessive sagging of the formwork during construction, which would result in an unanticipated increase in the weight of the concrete slab.

Deflection limits are specified to ensure adequate cover for reinforcing steel and to account for all dead load in the design.

C9.7.4.2

For steel stay-in-place formwork, it has been common to provide an allowance for the weight of the form and additional concrete, with the provision added to the contract documents that if the allowance is exceeded by the Contractor's choice, the Contractor is responsible for showing that the effects on the rest of the bridge are acceptable or providing additional strengthening as needed at no cost to the Owner. The customary allowance has been 0.015 ksf, but this should be reviewed if form spans exceed about 10.0 ft.

9.7.4.3—Concrete Formwork

9.7.4.3.1—Depth

The depth of stay-in-place concrete should neither exceed 55 percent of the depth of the finished deck slab nor be less than 3.5 in.

9.7.4.3.2—Reinforcement

Concrete formwork panels may be prestressed in the direction of the design span.

If the precast formwork is prestressed, the strands may be considered as primary reinforcement in the deck slab.

Transfer and development lengths of the strands shall be investigated for conditions during construction and in service.

Prestressing strands and/or reinforcing bars in the precast panel need not be extended into the cast-in-place concrete above the beams.

If used, bottom distribution reinforcement may be placed directly on the top of the panels. Splices in the top primary reinforcement in deck slab shall not be located over the panel joints.

The concrete cover below the strands should not be less than 0.75 in.

9.7.4.3.3—Creep and Shrinkage Control

The age of the panel concrete at the time of placing the cast-in-place concrete shall be such that the difference between the combined shrinkage and creep of the precast panel and the shrinkage of the cast-in-place concrete is minimized.

The upper surface of the panels shall be specified to be roughened in such a manner as to ensure composite action with the cast-in-place concrete.

9.7.4.3.4—Bedding of Panels

The ends of the formwork panels shall be supported on a continuous mortar bed or shall be supported during construction in such a manner that the cast-in-place concrete flows into the space between the panel and the supporting component to form a concrete bedding.

C9.7.4.3.1

Thousands of bridges have successfully been built with a depth ratio of 43 percent or somewhat higher; 55 percent is believed to be a practical limit, beyond which cracking of the cast-in-place concrete at the panel interface may be expected.

C9.7.4.3.2

The transfer and development lengths for epoxy-coated strands with alkali-resistant hard particles embedded in the coating may be less than that for uncoated strands. Where epoxy-coated strands are used, this value should be determined by testing.

Tests indicate no difference between constructions with and without reinforcement extended into the cast-in-place concrete over the beams (Bieschke and Klingner, 1982). The absence of extended reinforcement, however, may affect transverse load distribution due to a lack of positive moment continuity over the beams or may result in reflective cracking at the ends of the panel. In addition to transverse cracking, which usually occurs at the panel joints due to creep and shrinkage, the latter may appear unseemly and/or make the construction of this type of deck questionable where deicing salts are used.

C9.7.4.3.3

The objective of this Article is to minimize interface shear stresses between the precast panel and the cast-in-place concrete and to promote good bond. Normally, no bonding agents and/or mechanical connectors are needed for composite action.

C9.7.4.3.4

Setting screws, bituminous fiber boards, neoprene glands, etc., may be appropriate as temporary supports. In the past, some jurisdictions have had bad experience where prestressed concrete panels were supported only by flexible materials. Creep due to prestress had apparently pulled the panel ends away from cast-in-place concrete. Load was transferred to the flexible panel supports, which compressed, resulting in excessive reflective cracking in the cast-in-place concrete.

9.7.5—Precast Deck Slabs on Girders**9.7.5.1—General**

Both reinforced and prestressed precast concrete slab panels may be used. The depth of the slab, excluding any provision for grinding, grooving, and sacrificial surface, shall not be less than 7.0 in.

9.7.5.2—Transversely Joined Precast Decks

Flexurally discontinuous decks made from precast panels and joined together by shear keys may be used. The design of the shear key and the grout used in the key shall be approved by the Owner. The provisions of Article 9.7.4.3.4 may be applicable for the design of bedding.

9.7.5.3—Longitudinally Post-Tensioned Precast Decks

The precast components may be placed on beams and joined together by longitudinal post-tensioning. The minimum average effective prestress shall not be less than 0.25 ksi.

The transverse joint between the components and the block-outs at the coupling of post-tensioning ducts shall be specified to be filled with a nonshrink grout having a minimum compressive strength of 5.0 ksi at 24 hours.

Block-outs shall be provided in the slab around the shear connectors and shall be filled with the same grout upon completion of post-tensioning.

C9.7.5.2

The shear keys tend to crack due to wheel loads, warping, and environmental effects, leading to leaking of the keys and decreased shear transfer. The relative movement between adjacent panels tends to crack the overlay, if present. Therefore, this construction is not recommended for the regions where the deck may be exposed to salts.

C9.7.5.3

Decks made flexurally continuous by longitudinal post-tensioning are the more preferred solution because they behave monolithically and are expected to require less maintenance on the long-term basis.

The post-tensioning ducts should be located at the center of the slab cross-section. Block-outs should be provided in the joints to permit the splicing of post-tensioning ducts.

Panels should be placed on the girders without mortar or adhesives to permit their movement relative to the girders during prestressing. Panels can be placed directly on the girders or located with the help of shims of inorganic material or other leveling devices. If the panels are not laid directly on the beams, the space therein should be grouted at the same time as the shear connector block-outs.

A variety of shear key formations has been used in the past. Recent prototype tests indicate that a “V” joint may be the easiest to form and to fill.

9.7.6—Deck Slabs in Segmental Construction**9.7.6.1—General**

The provisions of this Article shall apply to the top slabs of post-tensioned girders whose cross-sections consist of single or multicell boxes. The slab shall be analyzed in accordance with the provisions of Article 4.6.2.1.6.

9.7.6.2—Joints in Decks

Joints in the decks of precast segmental bridges may be dry joints, epoxied match-cast surfaces, or cast-in-place concrete.

Dry joints should be used only in regions where deicing salts are not applied.

C9.7.6.2

Dry joints in the deck, with or without a nonstructural sealant, have been observed to permit percolation of water due to shrinkage as well as creep and temperature-induced warping of segments. Both epoxied match-cast and cast-in-place concrete joints permitted herein should produce

The strength of cast-in-place concrete joints shall not be less than that of the precast concrete. The width of the concrete joint shall permit the development of reinforcement in the joint or coupling of ducts if used, but in no case shall it be less than 12.0 in.

9.8—METAL DECKS

9.8.1—General

Metal decks shall be designed to satisfy the requirements of Sections 6 and 7. The tire contact area shall be determined as specified in Article 3.6.1.2.5.

9.8.2—Metal Grid Decks

9.8.2.1—General

Grid deck shall be composed of main elements that span between beams, stringers, or cross-beams and secondary members that interconnect and span between the main elements. The main and secondary elements may form a rectangular or diagonal pattern and shall be securely joined together. All intersections of elements in open grid floors, partially filled grid decks, and unfilled grid decks composite with reinforced concrete slabs shall be welded.

Force effects may be determined using one of the following methods:

- The approximate methods specified in Article 4.6.2.1, as applicable;
- Orthotropic plate theory;
- Equivalent grid; or
- Design aids provided by the manufacturers, if the performance of the deck is documented and supported by sufficient technical evidence.

One of the accepted approximate methods is based on transformed cross-section area. Mechanical shear transfer devices, including indentations, embossment, sand coating of surface, and other appropriate means may be used to enhance the composite action between elements of the grid and the concrete fill.

If a filled or partially filled grid deck, or an unfilled grid deck composite with reinforced concrete slab is considered to be composite with its supporting members for the purpose of designing those members, the effective width of slab in composite section shall be as specified in Article 4.6.2.6.1.

watertight joints. The 12.0-in. cast-in-place closure joint is believed to provide a better riding profile if the deck is not overlaid.

A combination joint in which only the deck part of a match-cast joint is epoxied should be avoided.

C9.8.2.1

Research has shown that welds between elements in partially filled grids “may be very important to the survival of the cross bar” (Gangarao et al., 1992).

Laboratory tests have shown that section properties of filled and partially filled grids, computed by the transformed area method, are conservative (Gangarao et al., 1992). Tests have also demonstrated that a monolithic concrete overpour may be considered fully effective in determining section properties.

Filled and partially filled grid decks and unfilled grid decks composite with reinforced concrete slabs have better potential for composite action with the supporting components due to their considerable in-plane rigidity.

In computing section properties, omit any effect of concrete in tension (e.g., below the neutral axis in positive bending, and above the neutral axis in negative bending).

The modular ratios may be applied to the composite action of concrete fill with grid deck in flexure and to the composite action between the deck and its supporting beams.

Field tests of systems consisting of unfilled grid decks composite with reinforced concrete slabs and stringers or floorbeams demonstrate significant levels of composite

action, with the effective width being at least 12.0 times the overall thickness of the deck, including the grid portion and the structural reinforced concrete slab.

9.8.2.2—Open Grid Floors

Open grid floors shall be connected to the supporting components by welding or by mechanically fastening at each main element. Where welding is used to make this connection, a single-sided 3.0-in. long weld or a 1.5-in. weld on each side of the main element may be used.

Unless evidence is provided to the contrary, welding within open grid floors should be considered as a Category E detail, and the provisions of Article 6.6 shall apply.

Ends and edges of open grid floors that may be exposed to vehicular traffic shall be supported by closure bars or other effective means.

C9.8.2.2

Long-term experience indicates that even where there is an apparently insignificant degree of composite action between the deck and its supporting components, high stresses may develop at their interface, resulting in local failures and separation of the deck. Therefore, the requirement to connect at each intersection of a main bar, as indicated, applies even to open grid floors.

9.8.2.3—Filled and Partially Filled Grid Decks

9.8.2.3.1—General

These decks shall consist of a metal grid or other metal structural system filled either completely or partially with concrete.

The provisions of Article 9.8.2.1 shall apply to filled and partially filled grid decks.

Where possible, a 1.75-in. thick structural overfill should be provided.

Filled and partially filled grids shall be attached to supporting components by welding or shear studs to transfer shear between the two surfaces.

C9.8.2.3.1

Full-scale tests on systems consisting of partially filled grid decks and stringers demonstrated significant levels of composite action, with the effective width being at least 12.0 times the depth of the deck. Under load, the deck strain readings across the width of the deck were nearly uniform, with extremely small slip recorded at the deck-stringer interface.

In order to activate the deck in composite action, large shear forces need be resisted at the interface. A preferred method of shear transfer is by welded studs encased in a concrete haunch, similar to that illustrated in Figure C9.8.2.3.1-1.

Figure C9.8.2.3.1-1—An Acceptable Shear Connection of Partially and Fully Filled Grid Decks to Beams

9.8.2.3.2—Design Requirements

Design of filled and partially filled grid decks shall be in accordance with the provisions of Article 9.8.2.1 and Article 4.6.2.1.8.

The concrete portion of filled and partially filled grid decks shall be in accordance with the general provisions of Section 5 relating to long-term durability and integrity.

For cast-in-place applications, weight of concrete fill shall be assumed to be carried solely by the metal portion of the deck. The transient loads and superimposed permanent loads may be assumed to be supported by the grid bars and concrete fill acting compositely. A structural overfill may be considered as part of the composite structural deck. Where a structural overfill is provided, the design depth of the deck shall be reduced by a provision for loss that is expected as a result of grinding, grooving, or wear of the concrete.

9.8.2.3.3—Fatigue and Fracture Limit State

All connections among the elements of the steel grid in a fully filled grid deck or the connections within the concrete fill of a partially filled grid deck need not be investigated for fatigue in the local negative moment region of the deck (e.g., negative moment in the deck over a longitudinal stringer or floorbeam) when the deck is designed with a continuity factor of 1.0.

C9.8.2.3.2

The presence of a composite structural overlay improves both the structural performance and riding quality of the deck.

C9.8.2.3.3

Fully filled and partially filled steel grid decks must be checked for fatigue only in the positive moment region (mid-span of the deck). However, the deck fatigue moment should be calculated for a simple span configuration ($C = 1.0$) regardless of the actual span configuration.

The fatigue category to be used for fatigue investigation should be determined by appropriate laboratory testing in positive and negative bending. The fatigue category for welds and punchouts shall not be taken as better than Category C, which has been shown by testing to be appropriate for most details of grid decks constructed with concrete.

The small fillet welds used in the fabrication of grid decks are generally less than 1.5 in. long, but are not considered “tack welds.” In grid decks, “tack welds” refer only to small welds used to attach sheet metal pans that

9.8.2.4—Unfilled Grid Decks Composite with Reinforced Concrete Slabs

9.8.2.4.1—General

An unfilled grid deck composite with reinforced concrete slab consists of a reinforced concrete slab that is cast on top of and is composite with an unfilled steel grid. Composite action between the concrete slab and the grid deck shall be ensured by providing shear connectors or other means capable of resisting horizontal and vertical components of interface shears.

Composite action between the grid deck and the supporting components should be ensured by mechanical shear connectors.

Unless otherwise specified, provisions of Article 9.8.2.1 shall apply.

Discontinuities and cold joints in such decks should be kept to a minimum.

serve only as forms for concrete poured onto or into the grid.

Where possible, form pans should be attached by means other than tack welding.

C9.8.2.4.1

This bridge deck combines the attributes of a concrete deck and a steel grid deck.

An acceptable way of providing composite action between the deck and the supporting components is shown in Figure C9.8.2.4.1-1.

Figure C9.8.2.4.1-1—An Acceptable Shear Connection of Unfilled Grid Decks Composite with Reinforced Concrete Slabs to Beams

C9.8.2.4.2

For the purpose of design, the deck can be subdivided into intersecting sets of composite concrete/steel beams.

9.8.2.4.2—Design

Design of unfilled grid decks composite with reinforced concrete slabs shall be in accordance with the provisions of Article 9.8.2.1 and Article 4.6.2.1.8. The design depth of the deck shall be reduced by a provision for loss that is expected as a result of grinding, grooving, or wear of the concrete.

The reinforced concrete portion of unfilled grid decks composite with reinforced concrete slabs shall be in accordance with the general provisions of Section 5 relating to long-term durability and integrity.

In the concrete slab, one layer of reinforcement in each principal direction may be used.

For cast-in-place applications, weight of concrete slab shall be assumed to be carried solely by the grid portion of the deck. The transient loads and superimposed permanent loads may be assumed to be supported by the composite section.

The interface between the concrete slab and the metal system shall satisfy the provisions of Article 6.10.10. Acceptable methods of shear connection shall include tertiary bars to which 0.5-in. diameter rebar or round studs have been welded, or the punching of holes at least 0.75 in. in size in the top portion of the main bars of the grid which are embedded in the reinforced concrete slab by a minimum of 1.0 in.

9.8.2.4.3—Fatigue Limit State

The internal connection between the elements of the steel grid in unfilled grid decks composite with reinforced concrete slabs shall be investigated for fatigue.

Unless evidence is provided to the contrary, tack welds attaching horizontal form pans to metal grids shall be considered Category E' details.

The composite reinforced concrete slab shall be included in the calculation of stress range.

C9.8.2.4.3

The fatigue category to be used for fatigue investigation should be determined by appropriate laboratory testing in positive and negative bending. The fatigue category for welds and punchouts shall not be better than Category C, which has been shown by testing to be appropriate for most details of grid decks constructed with concrete.

The small fillet welds used in the fabrication of grid decks are generally less than 1.5 in. long, but are not considered "tack welds." In grid decks, "tack welds" refer only to small welds used to attach sheet metal pans that serve only as forms for concrete poured onto or into the grid.

Where possible, form pans should be attached by means other than tack welding.

9.8.3—Orthotropic Steel Decks

9.8.3.1—General

Orthotropic steel decks shall consist of a deck plate stiffened and supported by longitudinal ribs and transverse floorbeams. The deck plate shall act as a common flange of the ribs, the floorbeams, and the main longitudinal components of the bridge.

In rehabilitation, if the orthotropic deck is supported by existing floorbeams, the connection between the deck and the floorbeam should be designed for full composite action, even if the effect of composite action is neglected in the design of floorbeams. Where practical, connections suitable to develop composite action between the deck and the main longitudinal components should be provided.

C9.8.3.1

The intent of this Article is to ensure the structural integrity of the deck and its structural participation with the cross-beams and the primary longitudinal components, as appropriate. Any structural arrangement in which the orthotropic deck is made to act independently from the main components is undesirable.

9.8.3.2—Wheel Load Distribution

A 45-degree distribution of the tire pressure may be assumed to occur in all directions from the surface contact area to the middle of the deck plate. The tire footprint shall be as specified in Article 3.6.1.2.5.

C9.8.3.2

The 45-degree distribution is the traditional, conservative assumption.

9.8.3.3—Wearing Surface

The wearing surface should be regarded as an integral part of the total orthotropic deck system and shall be specified to be bonded to the top of the deck plate.

The contribution of a wearing surface to the stiffness of the members of an orthotropic deck may be considered

C9.8.3.3

Wearing surfaces acting compositely with the deck plate may reduce deformations and stresses in orthotropic decks.

The deck stiffening effect of the wearing surface is dependent upon its thickness, the elastic modulus which is

if structural and bonding properties are satisfactorily demonstrated over the temperature range of -20°F to $+120^{\circ}\text{F}$. If the contribution of the wearing surface to stiffness is considered in the design, the required engineering properties of the wearing surface shall be indicated in the contract documents.

Force effects in the wearing surface and at the interface with the deck plate shall be investigated with consideration of engineering properties of the wearing surface at anticipated extreme service temperatures.

The long-term composite action between deck plate and wearing surface shall be documented by both static and cyclic load tests.

For the purpose of designing the wearing surface and its adhesion to the deck plate, the wearing surface shall be assumed to be composite with the deck plate, regardless of whether the deck plate is designed on that basis.

dependent on temperature and the load application, e.g., static or dynamic, and bond characteristics.

The combination of temperature and live load effects has resulted in debonding of some wearing surfaces in the field, which should be regarded as failure of the wearing surface. The Designer should consider past experience in selection of a wearing surface and in determination of its long-term contribution to the structural system.

Wearing surface cracking is related to stresses exceeding tensile strength of surfacing material. Flexural stresses in surfacing may be reduced by limiting local deck flexibility, as indicated in Article 2.5.2.6.2. Safety against surfacing cracking may be best assured by using surfacing materials with semiplastic properties or with low elastic modulus not subject to much variation with temperature.

The wearing surface plays an important role in improving skid resistance, distributing wheel loads, and protecting the deck against corrosion and abuse.

Selection or design of a wearing surface should include evaluation of the following functional requirements:

- Sufficient ductility and strength to accommodate expansion, contraction, and imposed deformation without cracking or debonding;
- Sufficient fatigue strength to withstand flexural stresses due to composite action of the wearing surface with the deck plate resulting from local flexure;
- Sufficient durability to resist rutting, shoving, and wearing;
- Imperviousness to water and motor vehicle fuels and oils;
- Resistance to deterioration from deicing salts; and
- Resistance to aging and deterioration due to solar radiation.

9.8.3.4—Analysis of Orthotropic Decks

9.8.3.4.1—General

Design of orthotropic decks shall be based on appropriate use of the three levels of analysis specified herein. The fatigue limit state shall be investigated using at least one of the three levels of design specified in Articles 9.8.3.4.2 through 9.8.3.4.4. Strength, service, and extreme event limit states, as appropriate, and constructability criteria shall be investigated using Level 2 design.

C9.8.3.4.1

The updated design approach for orthotropic deck bridges is based on the following considerations:

- Simplified methods do not currently exist which can evaluate the fatigue limit state at all fatigue-sensitive details;
- Design cannot be accomplished by detailing requirements alone due to a lack of tested and established standard deck panel details;
- Refined analysis for new designs will add engineering cost and potentially limit use for routine span arrangements; and
- Verification testing of every design adds unnecessary cost and has the potential to delay construction.

Hence, design verification of orthotropic steel bridge decks requires a new approach. Since many of the

controlling aspects of orthotropic deck panel design are local rather than global demands, a well-designed and detailed panel has the potential to be reused in future applications and become a standardized modular component. Therefore, the required effort for design can vary depending on the application and available test data. These different levels of required effort for design or design levels are summarized as follows:

- Level 1 design is based on little or no structural analysis but is done by selection of details that are verified to have adequate resistance by experimental testing (new or previous). When appropriate laboratory tests have been conducted for previous projects or on specimens similar in design and details to those proposed for a new project, the previous tests may be used as the basis for the design on the new project. All details must provide a level of safety consistent with the *AASHTO LRFD Bridge Design Specifications*.
- Level 2 design is based on simplified one-dimensional or two-dimensional analysis of certain panel details where such analysis is sufficiently accurate or for certain details that are similar to previously tested details as described in Level 1. Calculations consider only nominal stresses and not local stress concentrations. This is primarily intended to allow incremental improvement of previously tested details as verified by Level 1. Approximate analysis of both open-rib and closed-rib decks may be based on the Pelikan–Esslinger method presented by Wolchuck (1963) and Troitsky (1987). This method gives conservative values of global force effects in the orthotropic deck supported on longitudinal edge girders. Load distribution of adjacent transversely located wheel loads on decks with closed ribs is discussed in AISC (1963).
- Level 3 design is based on refined three-dimensional analysis of the panel to quantify the local stresses to the most accurate extent reasonably expected from a qualified design engineer experienced in refined analysis. Level 3 designs will be dictated by the requirements to provide safety against fatigue failure. If no test data is available for a panel, design Level 3 is required unless it can be proven that the local distortional mechanisms (floorbeam distortion and rib distortion) will not lead to fatigue cracking. For design of panels for bridge redecking applications, design Level 3 should always be used unless an exception is approved by the Owner.

Level 3 design is an extension of current AASHTO methodology for fatigue evaluation by nominal stresses. The proposed Level 3 design method is also similar to methodology applied by the American Petroleum Institute (API) and American Welding Society (AWS, 2004) and is well documented by the International Institute of Welding

(IIW, 2007). It is used extensively for the fatigue evaluation of tubular structures and plate-type structures with complex geometries by various industries, where there is no clearly defined nominal stress due to complicated geometric effects, conditions very similar to orthotropic deck details. This approach recognizes that fatigue damage is caused by stress raisers that exist at details and attempts to quantify them by refined analysis rather than accounting for the stresses risers using classification into general categories.

Research has demonstrated that evaluating the local structural stress and evaluating the stress range with AASHTO Category C provides a reliably conservative assessment of the weld toe cracks at orthotropic deck panel welded joints subjected to distortional stresses. The AASHTO Category C curve is similar to the curves provided in the Eurocode (ECS, 1992) and IIW (2007) for evaluation of welded details. Furthermore, research by Dexter et al. (1994) found that the AASHTO Category C curve provides the 97.5 percent survival lower bound for welded details on flexible plates subjected to combined in-plane and out-of-plane stresses in all cases where local stress measured 5 mm from weld toe was used for the fatigue life stress range. The work by Connor and Fisher (2006) also found similar results. This approach is predicated on the modeling and stress analysis being conducted by the method prescribed by Level 3 design.

The procedures for calculating local structural stress for welded connections are representative of a mesh sizing where the length and width of each individual shell or solid element is equivalent to the thickness, t , of the connected component. For modeling with other mesh spacing, different procedures are required for extrapolation of the local structural stress and are presented in more detail in *Recommendations for Fatigue Design of Welded Joints and Components* (IIW, 2007) and *Manual for Design, Construction, and Maintenance of Orthotropic Steel Deck Bridges* (FHWA, 2012).

9.8.3.4.2—Level 1 Design

Orthotropic deck panels and details verified by appropriate full-scale laboratory testing may be used without consideration of design Levels 2 and 3 provided the testing protocol envelopes the structural design loads and stresses for the new application. Test loading should be equivalent to the maximum truck load; stress ranges at details should accurately simulate expected in-service demands and should have accurate boundary conditions. For finite fatigue life design, the resistance shall provide 97.5 percent confidence of survival. For infinite fatigue life design, the constant amplitude fatigue limit (CAFL) should be exceeded no more than one in 10,000 cycles (0.01 percent). Full-scale tests should include a minimum of two rib spans with three floorbeams.

Previously verified Level 1 designs that have been verified by laboratory testing may be used as the basis for

design on new projects without additional testing, subject to approval by the Owner.

9.8.3.4.3—Level 2 Design

9.8.3.4.3a—General

Details not subjected to local distortional mechanisms similar to those previously proven by appropriate laboratory testing or those that have been proven effective by Level 3 designs and long-term observation while subjected to the appropriate loads may be verified considering only nominal stresses determined from simplified analysis.

9.8.3.4.3b—Decks with Open Ribs

The rib may be analyzed as a continuous beam supported by the floorbeams.

For rib spans not exceeding 15.0 ft, the load on the one rib due to wheel loads may be determined as the reaction of transversely continuous deck plate supported by rigid ribs. For rib spans greater than 15.0 ft, the effect of rib flexibility on the lateral distribution of wheel loads may be determined by elastic analysis.

For rib spans less than 10.0 ft or for decks with shallow floorbeams, the flexibility of the floorbeams shall be considered in calculating force effects in the ribs.

9.8.3.4.3c—Decks with Closed Ribs

For the global analysis of decks with closed ribs, the semi-empirical Pelikan–Esslinger method may be used. The load effects on a closed rib with a span not greater than 20.0 ft may be calculated from wheel loads placed over one rib only, without regard for the effects of adjacent transversely located wheel loads.

For longer rib spans, appropriate corrections of load effects on ribs shall be calculated.

9.8.3.4.4—Level 3 Design

New orthotropic details may be designed using refined three-dimensional analysis as defined in Article 4.6.3.2.3 and as specified below. For fatigue analysis, the structural modeling techniques shall include:

- use of shell or solid elements with acceptable formulation to accommodate steep stress gradients,
- mesh density of $t \times t$, where t is the thickness of the plate component, and
- local structural stresses shall be determined as specified below.

For fatigue design, the local structural stress shall be used for comparison to the nominal fatigue resistance. Local structural stress at welded connections shall be measured perpendicular to the weld toe and is determined using reference points in the finite element model and

extrapolation as shown in Figure 9.8.3.4.4-1. The reference points shall be located at the surface of elements at a distance of $0.5t$ and $1.5t$ measured perpendicular from the weld toe, respectively, with the local structural stress, f_{ls} , determined as:

$$f_{ls} = 1.5f_{0.5} - 0.50f_{1.5} \quad (9.8.3.4.4-1)$$

where:

$f_{0.5}$ = the surface stress at a distance of $0.5t$ from the weld toe (ksi)

$f_{1.5}$ = the surface stress at a distance of $1.5t$ from the weld toe (ksi)

Design Level 3 shall be required for all bridge redecking applications unless the redecking procedure can be demonstrated as meeting the requirements of Article 9.8.3.4.1 and is approved by the Owner.

Figure 9.8.3.4.4-1—Local Structural Stress for Level 3 Design of Orthotropic Decks

9.8.3.5—Design

9.8.3.5.1—Superposition of Local and Global Effects

C9.8.3.5.1

In calculating extreme force effects in the deck, the combination of local and global effects should be determined as specified in Article 6.14.3.

The orthotropic deck is part of the global structural system, and, therefore, participates in distributing global stresses. These stresses may be additive to those generated in the deck locally. The axles of the design truck or the design tandem are used for the design of decks, whereas the rest of the bridge is proportioned for combinations of the design truck, the design tandem, and the design lane load. The governing positions of the same load for local and global effects could be quite different. Therefore, the Designer should analyze the bridge for both load regimes separately, apply the appropriate dynamic load allowance factor, and use the one that governs.

9.8.3.5.2—Limit States

9.8.3.5.2a—General

Orthotropic decks shall be designed to meet the requirements of Section 6 at all applicable limit states unless otherwise specified herein.

9.8.3.5.2b—Service Limit State

At the service limit state, the deck shall satisfy the requirements as specified in Article 2.5.2.6.

9.8.3.5.2c—Strength Limit State

At the strength limit state for the combination of local and global force effects, the provisions of Article 6.14.3 shall apply.

The effects of compressive instability shall be investigated at the strength limit state. If instability does not control, the resistance of orthotropic plate deck shall be based on the attainment of yield strength at any point in the cross-section.

9.8.3.5.2d—Fatigue Limit State

Structural components shall be checked for fatigue in accordance with the appropriate design level as specified in Article 9.8.3.4. The provisions of Article 6.6.1.2 shall apply for load-induced fatigue.

With the Owner's approval, application of less stringent fatigue design rules for interior traffic lanes of multilane decks subjected to infrequent traffic may be considered.

C9.8.3.5.2a

Tests indicate a large degree of redundancy and load redistribution between first yield and failure of the deck. The large reduction in combined force effects is a reflection of this performance.

C9.8.3.5.2b

Service Limit State I must be satisfied for overall deflection limits and is intended to prevent premature deterioration of the wearing surface.

Service Limit State II is for the design of bolted connections against slip for overload and should be considered for the design of the rib and floorbeam splices. The remaining limit states are for tensile stresses in concrete structures and can be ignored.

C9.8.3.5.2c

The deck, because it acts as part of the global structural system, is exposed to in-plane axial tension or compression. Consequently, buckling should be investigated.

Strength design must consider the following demands: rib flexure and shear, floorbeam flexure and shear, and panel buckling. The rib, including the effective portion of the deck plate, must be evaluated for flexural and shear strength for its span between the floorbeams. The floorbeam, including the effective portion of the deck plate, must be evaluated for flexural and shear strength for its span between primary girders or webs. The reduction in floorbeam cross-section due to rib cutouts must be considered. When the panel is part of a primary girder flange, the panel must be evaluated for axial strength based on stability considerations.

Strength Limit IV condition is only expected to control where the orthotropic deck is integral with a long-span bridge superstructure.

C9.8.3.5.2d

Experience has shown that fatigue damage on orthotropic decks occurs mainly at the ribs under the truck wheel paths in the exterior lanes.

For Level 1 design, test loads should be representative of the fatigue truck factored for the Fatigue I load combination and the critical details of the test specimen(s) should simulate both the expected service conditions and the appropriate boundary conditions; verification of these details is sufficient in lieu of a detailed refined fatigue analysis.

9.8.3.6—Detailing Requirements

9.8.3.6.1—Minimum Plate Thickness

Minimum plate thickness shall be determined as specified in Article 6.7.3.

9.8.3.6.2—Closed Ribs

The one-sided weld between the web of a closed rib and the deck plate shall have a minimum penetration of 60 percent and no blow-through, and shall be placed with a tight fit providing less than or equal to a 0.02 in. gap prior to welding. The weld throat shall be greater than or equal to the rib wall thickness.

C9.8.3.6.2

Historically, the rib-to-deck plate weld has been specified as a one-sided partial penetration weld with minimum 80 percent penetration. Achieving a minimum of 80 percent penetration without blow-through is very difficult and fabricators have often failed to consistently satisfy this requirement. Fatigue tests have demonstrated superior behavior of the weld when the weld throat size is equal to or exceeds the thickness of the rib, with 60 percent or more of the rib-plate thickness fused (Fisher and Barsom, 2015).

The root gap is also a parameter that may influence performance. Research has shown that fatigue resistance of the weld is clearly improved when the root gap is closed in the final condition. When there is full contact, it appears that the root is protected and cracking is prevented. Shop experience indicates that using a tight fit prior to welding will also help prevent weld blow-through. Kolstein (2007) suggests the limit of 0.02 in. and this is adopted in these Specifications.

Additionally, melt-through of the weld is a quality issue that must be controlled. Fatigue tests on a limited number of samples (Sim and Uang, 2007) indicate that the performance of locations of melt-through is greater than or equal to those created by the notch condition of the 80 percent penetration. However, there are legitimate concerns that excessive melt-through may provide potential fatigue initiation sites and as such it should be avoided if possible. As such, the proposed detailing criteria is that the rib-to-deck weld be one-sided with a 60 percent minimum penetration and no blow-through, with the weld throat greater than or equal to the rib thickness, and with a tight fit providing less than or equal to a 0.02 in. gap prior to welding. Additional details of the weld joint should be left for the fabricator to develop.

9.8.3.6.3—Welding to Orthotropic Decks

Welding of attachments, utility supports, lifting lugs, or shear connectors to the deck plate or ribs shall require approval by the Engineer of Record for the deck system.

9.8.3.6.4—Deck and Rib Details

Deck and rib splices shall either be welded or mechanically fastened by high-strength bolts. Ribs shall be run continuously through cutouts in the webs of floorbeams, as shown in Figure 9.8.3.6.4-1. The following fabrication details shall be required by the contract documents as identified in Figure 9.8.3.6.4-1:

C9.8.3.6.4

Closed ribs may be trapezoidal, U-shaped, or V-shaped; the latter two are most efficient.

The floorbeam web cutouts at the intersections with the ribs may be with or without an additional free cutout at the bottom of the ribs. The former detail is generally preferable since it minimizes the rib restraint against

- a) No snipes (cutouts) in floorbeam web
- b) Welds to be wrapped around
- c) Grind smooth
- d) Combined fillet-groove welds may have to be used 1) in cases where the required size of fillet welds to satisfy the fatigue resistance requirements would be excessive if used alone or 2) to accomplish a ground termination.

Figure 9.8.3.6.4-1—Detailing Requirements for Orthotropic Decks

9.8.4—Orthotropic Aluminum Decks

9.8.4.1—General

Orthotropic aluminum decks shall consist of a deck plate stiffened and supported by rib extrusions. The ribs may be parallel or perpendicular to the direction of traffic.

The provisions of Article 9.8.3.2 through Article 9.8.3.3 shall apply, except that the wearing surface shall not be regarded as an integral part of the orthotropic deck for analysis and design of the deck or rib.

When an aluminum orthotropic deck is supported by components of another material, the differences in thermal expansion of the two materials and the potential for accelerated corrosion due to dissimilar metals shall be considered.

The structural interaction of an aluminum orthotropic deck with the existing structure shall be investigated.

9.8.4.2—Approximate Analysis

In lieu of more precise information, the effective width of deck plate acting with a rib shall not exceed the rib spacing or one-third of the span.

The flexibility of the supports shall be considered in determining the longitudinal moments in continuous decks.

rotation in its plane and associated stresses in the welds and in the floorbeam web.

If the bottom cutout depth, c , is small enough, the rotation of the rib is restrained and considerable out-of-plane stresses are introduced in the floorbeam web when the floorbeam is shallow. Local secondary stresses are also introduced in the rib walls by the interaction forces between the floorbeam webs and the rib walls and by secondary effects due to the small depth of cutout, c (Wolchuk and Ostapenko, 1992).

If the floorbeam web is deep and flexible, or where additional depth of the cutout would unduly reduce the shear strength of the floorbeam, welding all around the rib periphery may be appropriate (ECSC Report on Fatigue, 1995) (Wolchuk, 1999).

Fatigue tests suggested that open snipes in the floorbeam webs at the junctions of the rib walls with the deck plate may cause cracks in the rib walls. Therefore, a tight-fitting snipe and a continuous weld between the floorbeam web and the deck and rib wall plates appear to be preferable.

Open ribs may be flat bars, angles, tees, or bulb bars. Open-rib decks are less efficient and require more welding but are generally considered less risky to fabricate.

C9.8.4.1

Only one application of ribs placed perpendicular to traffic was known as of 1997. Therefore, little or no experience of in-service fatigue behavior exists, and complete investigation of load-induced and distortion-induced fatigue should be required for this application.

C9.8.4.2

In determining the transverse moments, the effects of the torsional rigidity of the ribs shall be included when the ribs are torsionally stiff and may be disregarded if the ribs are torsionally flexible.

For the analysis of decks with closed ribs, the provisions of Article 9.8.3.4.3c may be applied.

9.8.4.3—Limit States

Orthotropic decks shall be designed to meet the requirements of Section 7 at all applicable limit states.

At the service limit state, the deck shall satisfy the requirement of Article 2.5.2.6.

The longitudinal ribs, including an effective width of deck plate, shall be investigated for stability as individual beam-columns assumed as simply supported at transverse beams.

At the fatigue limit state, the deck shall satisfy the provisions of Article 7.6.

Regardless of whether the stress range is tensile, compressive, or reversal, maximum stress range shall be investigated for:

- Transverse direction at the rib-to-plate connection;
- Longitudinal direction;
- All bolted, welded end, and edge details; and
- Transverse direction at the rib-to-plate connection when the adjacent rib is loaded.

9.8.5—Corrugated Metal Decks

9.8.5.1—General

Corrugated metal decks should be used only on secondary and rural roads.

Corrugated metal decks shall consist of corrugated metal pans filled with bituminous asphalt or another approved surfacing material. The metal pans shall be positively fastened to the supporting components.

9.8.5.2—Distribution of Wheel Loads

A 45-degree distribution of the tire load from the contact area to the neutral axis of the corrugated metal pans may be assumed.

9.8.5.3—Composite Action

For contribution of the fill to composite action with the deck plate, the provisions of Article 9.8.3.3 shall apply.

Composite action of the corrugated metal deck pan with the supporting components may be considered only if the interface connections are designed for full composite action, and the deck is shown to resist the compressive forces associated with the composite action.

The transverse moments should be calculated in two stages: those due to the direct loading of the deck plate, assuming nondeflecting ribs, and those due to the transverse shear transfer resulting from the rib displacements. Stresses from these moments are then combined.

C9.8.4.3

This condition has been shown to control the design under certain geometrical conditions.

The maximum stress range is used for design because significant tensile residual stresses exist adjacent to most weldments, and gross compressive stresses may result in a net tensile stress range.

See Menzemer et al. (1987) for additional discussion.

C9.8.5.1

The intent of fastening the corrugated metal pans to the supporting components is to ensure the stability of both under transient loads.

C9.8.5.2

The 45-degree distribution is a traditional approach for most nonmetallic structural materials.

C9.8.5.3

Due to the sensitivity of the plate to temperature, corrosion, and structural instability, composite action should be utilized only if physical evidence is sufficient to prove that its functionality can be counted on for the specified design life.

9.9—WOOD DECKS AND DECK SYSTEMS

9.9.1—Scope

This Article shall apply to the design of wood decks supported by beams, stringers, or floorbeams or used as a deck system.

9.9.2—General

The provisions of Section 8 shall apply.

Materials used in wood decks and their preservative treatment shall meet the requirements of Sections 2, 5, 6, and 8.

The nominal thickness of plank decks shall not be less than 4.0 in. for roadways and 2.0 in. for sidewalks. The nominal thickness of wood decks other than plank decks shall not be less than 6.0 in.

9.9.3—Design Requirements

9.9.3.1—Load Distribution

Force effects may be determined by using one of the following methods:

- The approximate method specified in Article 4.6.2.1,
- Orthotropic plate theory, or
- Equivalent grid model.

If the spacing of the supporting components is less than either 36.0 in. or 6.0 times the nominal depth of the deck, the deck system, including the supporting components, shall be modeled as an orthotropic plate or an equivalent grid.

In stress-laminated decks satisfying the butt stagger requirements specified in Article 9.9.5.3, rigidity may be determined without deduction for the butt joints.

9.9.3.2—Shear Design

Shear effects may be neglected in the design of stress-laminated decks. In longitudinal decks, maximum shear shall be computed in accordance with the provisions of Article 8.7.

In transverse decks, maximum shear shall be computed at a distance from the support equal to the depth of the deck.

For both longitudinal and transverse decks, the tire footprint shall be located adjacent to, and on the span side of, the point of the span where maximum force effect is sought.

C9.9.1

This Article applies to wood decks and deck systems that are currently being designed and built in the United States and that have demonstrated acceptable performance. The supporting components may be metal, concrete, or wood.

C9.9.2

In laminated decks, large deviations in the thickness or extensive warping of the laminations may be detrimental regarding both strength and long-term performance. Although rough or full sawn material can be more economical than planed, the variations in dimensions can be quite large. If appropriate dimensional tolerances are not likely to be obtained, dressing of the components should be recommended.

C9.9.3.1

In wood decks with closely spaced supporting components, the assumption of infinitely rigid supports upon which approximate methods of analysis are based is not valid. Two-dimensional methods of analysis are, therefore, recommended to obtain force effects with reasonable accuracy.

C9.9.3.2

Shear problems in laminated wood decks are rare, as the inherent load sharing benefits of the multiple-member system are believed to be quite significant. The probability of simultaneous occurrence of potentially weak shear zones in adjacent laminates is low. Therefore, a multiple-member shear failure, which would be necessary to propagate shear splits in any one lamination, would be difficult to achieve.

With little test data available, no changes to the shear design for spike-laminated decks are being introduced.

9.9.3.3—Deformation

At the service limit state, wood decks shall satisfy the requirements specified in Article 2.5.2.6.

9.9.3.4—Thermal Expansion

The coefficient of thermal expansion of wood parallel to its fibers shall be taken as 0.000002 per °F.

Thermal effects may be neglected in plank decks and spike-laminated decks.

For stress-laminated and glued laminated panel decks made continuous over more than 400 ft, relative movements due to thermal expansion with respect to substructures and abutments shall be investigated.

9.9.3.5—Wearing Surfaces

Wood decks shall be provided with a wearing surface conforming to the provisions of Article 9.9.8.

9.9.3.6—Skewed Decks

Where the skew of the deck is less than 25 degrees, transverse laminations may be placed on the skew angle. Otherwise, the transverse laminations shall be placed normal to the supporting components, and the free ends of the laminations at the ends of the deck shall be supported by a diagonal beam or other suitable means.

9.9.4—Glued Laminated Decks

9.9.4.1—General

Glued laminated timber panel decks shall consist of a series of panels, prefabricated with water-resistant adhesives, that are tightly abutted along their edges.

Transverse deck panels shall be continuous across the bridge width.

If the span in the primary direction exceeds 8.0 ft, the panels shall be interconnected with stiffener beams as specified in Article 9.9.4.3.

9.9.4.2—Deck Tie-Downs

Where panels are attached to wood supports, the tie-downs shall consist of metal brackets that are bolted through the deck and attached to the sides of the supporting component. Lag screws or deformed shank spikes may be used to tie panels down to wood support.

Where panels are attached to steel beams, they shall be tied down with metal clips that extend over the beam flange and that are bolted through the deck.

C9.9.3.4

Generally, thermal expansion has not presented problems in wood deck systems. Except for the stress-laminated deck and tightly placed glued laminated panels, most wood decks inherently contain gaps at the butt joints that can absorb thermal movements.

C9.9.3.5

Experience has shown that unprotected wood deck surfaces are vulnerable to wear and abrasion, and they may become slippery when wet.

C9.9.3.6

With transverse decks, placement of the laminations on the skew is the easiest and most practical method for small skew angles, and cutting the ends of the laminations on the skew provides a continuous straight edge.

In longitudinal decks, except for stress-laminated wood, any skew angle can generally be accommodated by offsetting each adjacent lamination on the skew.

C9.9.4.1

In glued laminated decks built to date, transverse deck panels have been 3.0 to 6.0 ft wide, and longitudinal deck panels have been 3.5 to 4.5 ft wide. The design provisions are considered applicable only to the range of panel sizes given herein.

These design provisions are based upon development work carried out at the United States Department of Agriculture Forest Products Laboratory in the late 1970s.

This form of deck is appropriate only for roads having low to medium volumes of commercial vehicles.

C9.9.4.2

The methods of tie-down specified herein are based upon current practices that have proven to be adequate. Use of other methods require approval by Owner.

9.9.4.3—Interconnected Decks

9.9.4.3.1—Panels Parallel to Traffic

Interconnection of panels shall be made with transverse stiffener beams attached to the underside of the deck. The distance between stiffener beams shall not exceed 8.0 ft, and the rigidity, EI , of each stiffener beam shall not be less than 80,000 kip-in.². The beams shall be attached to each deck panel near the panel edges and at intervals not exceeding 15.0 in.

9.9.4.3.2—Panels Perpendicular to Traffic

Interconnection of panels may be made with mechanical fasteners, splines, dowels, or stiffener beams. Where used, the stiffener beams should be continuous over the full length of the span and should be secured through the deck within 6.0 in. of the edges of each panel and as required between edges.

When panels are interconnected with stiffener beams, the beams shall be placed longitudinally along the centerspan of each deck span. Provisions of Article 9.9.4.3.1 shall apply for the design of the stiffener beams.

The live load bending moment per unit width shall be determined in accordance with the provisions of Article 4.6.2.1.3.

9.9.4.4—Noninterconnected Decks

Decks not interconnected at their edges shall only be employed on secondary rural roads. No transfer of force effects at the panel edges shall be assumed in the analysis.

9.9.5—Stress-Laminated Decks

9.9.5.1—General

Stress-laminated decks shall consist of a series of wood laminations that are placed edgewise and post-tensioned together, normal to the direction of the lamination.

Stress-laminated decks shall not be used where the skew exceeds 45 degrees.

The contract documents shall require that the material be subjected to expansion baths to remove excess oils.

C9.9.4.3.1

Although the transverse stiffener beam ensures interpanel shear transfer of loads, some relative deflection will take place. Under frequent heavy loads, this relative deflection will cause reflective cracking of bituminous wearing surfaces.

C9.9.4.3.2

The doweling of the deck system is intended to prevent relative displacement of the glued laminated deck panels. A design procedure for dowels can be found in Ritter (1990). With proper prefabrication and construction, this doweled system has proven to be effective in preventing relative displacement between panels. However, in practice, problems with hole alignment and the necessity for field modifications may reduce their efficiency.

Using one longitudinal stiffener beam in each space between girders has proven to be both a practical and effective method of reducing relative displacements between transverse panels.

C9.9.4.4

The noninterconnected panel deck will likely cause reflective cracking in the wearing surface at the butt joints, even under relatively low levels of loading. It is appropriate only for roads having low volumes of commercial vehicles in order to avoid the extensive maintenance that the wearing surface may require.

C9.9.5.1

The majority of decks of this type include laminations which are 2.0 to 3.0 in. in thickness.

The increased load distribution and load sharing qualities of this deck, coupled with its improved durability under the effects of repeated heavy vehicles, make it the best choice among the several wood decks for high-volume road application (Csagoly and Taylor, 1979) (Sexsmith et al., 1979).

The structural performance of these decks relies on friction, due to transverse prestress, between the surfaces of the laminations to transfer force effects. Unlike spiked or bolted connections in wood, the friction-based performance of stress-laminated decks does not deteriorate with time under the action of repeated heavy loads.

9.9.5.2—Nailing

Each lamination shall be specified to be fastened to the preceding one by common or spiral nails at intervals not exceeding 4.0 ft. The nails shall be driven alternately near the top and bottom edges of the laminations. One nail shall be located near both the top and bottom at butt joints. The nails should be of sufficient length to pass through two laminations.

9.9.5.3—Staggered Butt Joints

Where butt joints are used, not more than one butt joint shall occur in any four adjacent laminations within a 4.0 ft distance, as shown in Figure 9.9.5.3-1.

Figure 9.9.5.3-1—Minimum Spacing of Lines of Butt Joints

9.9.5.4—Holes in Laminations

The diameter of holes in laminations for the prestressing unit shall not be greater than 20 percent of the lamination depth. Spacing of the holes along the laminations shall be neither less than 15.0 times the hole diameter nor less than 2.5 times the depth of the laminate.

Only drilled holes shall be permitted.

Experience seems to indicate that the use of waterborne preservatives can negatively affect the performance of stress-laminated decks. Wood treated with waterborne preservatives responds rapidly to the short-term changes in moisture conditions to which bridges are subjected frequently in most areas of North America. The attendant dimensional changes in the wood can result in substantial changes in the prestressing forces. Wood treated with oil-borne preservatives does not respond so readily to short-term changes in moisture conditions.

The preservative treatment for wood to be used in stress-laminated decks should be kept to the minimum specified in the standards given in Article 8.4.3. Excessive oils in the wood may be expelled after the deck is stressed and can contribute to higher prestress losses over a short period after construction.

C9.9.5.2

Nailing is only a temporary construction convenience in stress-laminated decks, and it should be kept as close to minimum requirements as possible. Excessive nailing may inhibit the build-up of elastic strains during transverse stressing, which could subsequently contribute to decreasing its effectiveness.

C9.9.5.3

Butt joint requirements are extreme values and are intended to allow for lamination lengths that are less than the deck length. Uniformly reducing or eliminating the occurrence of butt joints, distributing butt joints, or both will improve performance.

The implication of this provision is that laminations shorter than 16.0 ft cannot be used. If laminations longer than 16.0 ft are used, the spacing of butt joints is one-quarter of the length.

C9.9.5.4

These empirical limitations are intended to minimize the negative effects of hole size and spacing on the performance of the deck.

Punched holes can seriously affect the performance of the laminates by breaking the wood fibers in the vicinity of the holes.

9.9.5.5—Deck Tie-Downs

Decks shall be tied down at every support, and the spacing of the tie-downs along each support shall not exceed 3.0 ft. Each tie-down shall consist of a minimum of two 0.75-in. diameter bolts for decks up to and including 12.0 in. deep and two 1.0-in. diameter bolts for decks more than 12.0 in. deep.

9.9.5.6—Stressing

9.9.5.6.1—Prestressing System

New stressed wood decks shall be designed using internal prestressing. External prestressing may be used to rehabilitate existing nail-laminated decks and shall utilize continuous steel bulkheads.

In stress-laminated decks with skew angles less than 25 degrees, stressing bars may be parallel to the skew. For skew angles between 25 degrees and 45 degrees, the bars should be placed perpendicular to the laminations, and in the end zones, the transverse prestressing bars should be fanned in plan as shown in Figure 9.9.5.6.1-1 or arranged in a step pattern as shown in Figure 9.9.5.6.1-2.

Dimensional changes in the deck due to prestressing shall be considered in the design.

Anchorage hardware for the prestressing rods should be arranged in one of the three ways shown in Figure 9.9.5.6.1-3.

Figure 9.9.5.6.1-1—Fanned Layout of Prestressing Bars in End Zones of Skewed Decks—Illustrative Only

C9.9.5.5

The stress-laminated deck requires a more effective tie-down than toe-nailing or drift pins. It has a tendency to develop curvature perpendicular to the laminates when transversely stressed. Tie-downs using bolts or lag screws ensure proper contact of the deck with the supporting members.

C9.9.5.6.1

External and internal prestressing systems are shown in Figure 9.9.5.6.1-3. The internal system provides better protection to the prestressing element and lessens restriction to the application of wearing surfaces.

Generally, it is not necessary to secure timber decks to the supports until all the transverse stressing has been completed. There is the potential for extensive deformation when a deck is stressed over a very long length due to unintentional eccentricity of prestressing. It is recommended that restraints during stressing be provided when the width of the deck, perpendicular to the laminations, exceeds 50.0 times the depth of the deck for longitudinal decks and 40.0 times the depth of the deck for transverse decks. These restraints should not inhibit the lateral movement of the deck over its width during the stressing procedure.

Potential concentration of bearing stresses and sliding of the common bearing plate should be considered in conjunction with the fanned arrangement of prestressing elements shown in Figure 9.9.5.6.1-1.

Figure 9.9.5.6.1-2—Staggered Layout of Prestressing Bars in End Zones of Skewed Decks—Illustrative Only

A. EXTERNAL CHANNEL BULKHEAD ANCHORAGE CONFIGURATION.

B. CHANNEL BULKHEAD ANCHORAGE
CONFIGURATION.

C. BEARING PLATE ANCHORAGE CONFIGURATION.

Figure 9.9.5.6.1-3—Types of Prestressing Configurations

The isolated steel bearing plates should be used only on hardwood decks, or, where a minimum of two hardwood laminations are provided, on the outside edges of the deck.

9.9.5.6.2—Prestressing Materials

Prestressing materials shall comply with the provisions of Article 5.4.

9.9.5.6.3—Design Requirements

The steel–wood ratio, R_{sw} , shall satisfy:

$$R_{sw} = \frac{A_s}{sh} \leq 0.0016 \quad (9.9.5.6.3-1)$$

where:

- s = spacing of the prestressing elements (in.)
- h = depth of deck (in.)
- A_s = area of steel bar or strand (in.²)

The prestressing force per prestressing element (kip) shall be determined as:

$$P_{pt} = 0.1hs \quad (9.9.5.6.3-2)$$

The effective bearing area, A_B , on the wood directly under the anchorage bulkhead due to prestress shall be determined by considering the relative stiffness of the wood deck and the steel bulkhead. The bulkhead shall satisfy:

$$P_{BU} = \phi F A_B \geq P_{pt} \quad (9.9.5.6.3-3)$$

where:

- P_{BU} = factored compressive resistance of the wood under the bulkhead (kip)
- ϕ = resistance factor for compression perpendicular to grain as specified in Article 8.5.2.2
- F = nominal bearing resistance of wood across the grain, as specified in Table 9.9.5.6.3-1 (ksi)

Continuous steel bulkheads or hardwood laminations are required because they improve field performance. Isolated steel bearing plates on softwood decks have caused crushing of the wood, substantially increased stress losses and resulted in poor aesthetics.

C9.9.5.6.2

All prestressed wood decks built to date have utilized high-strength bars as the stressing elements. Theoretically, any prestressing system that can be adequately protected against corrosion is acceptable.

C9.9.5.6.3

The limitation on the steel–wood area ratio is intended to decrease prestress losses due to relaxation caused by wood and steel creep as well as deck dimensional changes due to variations in wood moisture content. Prestress losses are very sensitive to this ratio, and most existing structures have values less than 0.0016. A small area ratio of 0.0012 to 0.0014, coupled with an initial moisture content of less than 19 percent and proper preservative treatment, will ensure the highest long-term prestress levels in the deck.

The average compressive design stress represents the uniform pressure that is achieved away from the anchorage bulkhead. Limitation on compressive stress at maximum prestress minimizes permanent deformation in the wood. Increasing the initial compressive stress beyond these levels does not significantly increase the final compressive stress at the service limit state.

Eq. 9.9.5.6.3-2 is based on a uniform compressive stress of 0.1 ksi between the laminations due to prestressing. For structural analysis, a net compressive stress of 0.04 ksi, at the service limit state, may be assumed.

Relaxation of the prestressing system is time-dependent, and the extensive research work, along with the experience obtained on the numerous field structures, have shown that it is necessary to restress the system after the initial stressing to offset long-term relaxation effects. The optimum stressing sequence is as follows:

- Stress to full design level at time of construction,
- Restress to full design level not less than one week after the initial stressing, and
- Restress to full design level not less than four weeks after the second stressing.

After the first restressing, increasing the time period to the second restressing improves long-term stress retention. Subsequent restressings will further decrease the effects of long-term creep losses and improve stress retention.

Table 9.9.5.6.3-1—*F* Values for Prestressed Wood Decks

Species	<i>F</i> (ksi)
Douglas Fir–Larch	0.425
Hemlock Fir	0.275
Spruce–Pine–Fir	0.275
Eastern Softwoods	0.225
Mixed Southern Pine	0.375
Southern Pine	0.375
Spruce–Pine–Fir (South)	0.225
Northern Red Oak	0.600
Red Maple	0.400
Red Oak	0.550
Yellow Poplar	0.275

9.9.5.6.4—Corrosion Protection

Elements of the prestressing system shall be protected by encapsulation and/or surface coatings. The protective tubing shall be capable of adjusting at least ten percent of its length during stressing without damage.

C9.9.5.6.4

Elements of a suitable protection system are shown in Figure C9.9.5.6.4-1.

Figure C9.9.5.6.4-1—Elements of Corrosion Protection

C9.9.5.6.5

9.9.5.6.5—Railings

Railings shall not be attached directly either to any prestressing element or to bulkhead systems. The deck shall not be penetrated within 6.0 in. of a prestressing element.

Curb and railing attachment directly to any component of the stressing system increases the risk of failure in the event of vehicle impact.

9.9.6—Spike-Laminated Decks

9.9.6.1—General

Spike-laminated decks shall consist of a series of lumber laminations that are placed edgewise between supports and spiked together on their wide face with deformed spikes of sufficient length to fully penetrate four laminations. The spikes shall be placed in lead holes that are bored through pairs of laminations at each end and at intervals not greater than 12.0 in. in an alternating pattern near the top and bottom of the laminations, as shown in Figure 9.9.6.1-1.

Laminations shall not be butt spliced within their unsupported length.

C9.9.6.1

The use of spike-laminated decks should be limited to secondary roads with low truck volumes, i.e., *ADTT* significantly less than 100 trucks per day.

The majority of decks of this type have used laminations of 3.0 to 4.0 in. in thickness. The laminates are either assembled on site or are prefabricated into panels in preparation for such assembly.

The specified design details for lamination arrangement and spiking are based upon current practice. It is important that the spike lead holes provide a tight fit to ensure proper load transfer between laminations and to minimize mechanical movements.

Figure 9.9.6.1-1—Spike Layout for Spike-Laminated Decks

9.9.6.2—Deck Tie-Downs

Deck tie-downs shall be as specified in Article 9.9.4.2.

9.9.6.3—Panel Decks

The distribution widths for interconnected spike-laminated panels may be assumed to be the same as those for continuous decks, as specified in Section 4.

The panels may be interconnected with mechanical fasteners, splines, dowels, or stiffener beams to transfer shear between the panels. If stiffener beams are used, the provisions of Article 9.9.4.3 shall apply.

C9.9.6.3

The use of noninterconnected decks should be limited to secondary and rural roads.

It is important to provide an effective interconnection between panels to ensure proper load transfer. Stiffener beams, comparable to those specified for glued laminated timber panels, are recommended. Use of an adequate stiffener beam enables the spike-laminated deck to approach the serviceability of glue-laminated panel construction.

With time, the deck may begin to delaminate in the vicinity of the edge-to-edge panel joints. The load distribution provisions given for the noninterconnected panels are intended for use in the evaluation of existing noninterconnected panel decks and interconnected panel decks in which the interconnection is no longer effective.

9.9.7—Plank Decks

9.9.7.1—General

Wood plank decks shall consist of a series of lumber planks placed flatwise on supports. Butt joints shall be placed over supports and shall be staggered a minimum of 3.0 ft for adjacent planks.

C9.9.7.1

This type of deck has been used on low-volume roads with little or no heavy vehicles, and it is usually economical. However, these decks provide no protection against moisture to the supporting members; they will not readily accept and/or retain a bituminous wearing surface, and usually require continuous maintenance if used by heavy vehicles.

These decks should be limited to roads that carry little or no heavy vehicles or where the running surface is constantly monitored and maintained.

9.9.7.2—Deck Tie-Downs

On wood beams, each plank shall be nailed to each support with two nails of minimum length equal to twice the plank thickness.

On steel beams, planks shall be bolted to the beams or nailed to wood nailing strips. The strips should be at least 4.0 in. thick, and their width should exceed that of the beam flange. The strips should be secured with A 307 bolts at least 0.625 in. in diameter and placed through the flanges, spaced not more than 4.0 ft apart and no more than 1.5 ft from the ends of the strips.

9.9.8—Wearing Surfaces for Wood Decks

9.9.8.1—General

Wearing surfaces shall be of continuous nature and no nails, except in wood planks, shall be used to fasten them to the deck.

C9.9.8.1

Bituminous wearing surfaces are recommended for wood decks.

The surface of the wood deck should be free of surface oils to encourage adhesion and prevent bleeding of the preservative treatment through the wearing surface. Excessive bleeding of the treatment can seriously reduce the adhesion. The plans and specifications should clearly state that the deck material be treated using the empty cell process, followed by an expansion bath or steaming.

9.9.8.2—Plant Mix Asphalt

An approved tack coat shall be applied to wood decks prior to the application of an asphalt wearing surface. The tack coat may be omitted when a geotextile fabric is used, subject to the recommendations of the manufacturer.

When possible, a positive connection between the wood deck and the wearing surface shall be provided. This connection may be provided mechanically or with a geotextile fabric.

The asphalt should have a minimum compacted depth of 2.0 in. Where cross slope is not provided by the wood deck, a minimum of one percent shall be provided by the wearing surface.

9.9.8.3—Chip Seal

When a chip seal wearing surface is used on wood decks, a minimum of two layers should be provided.

C9.9.8.2

The application of a tack coat greatly improves the adhesion of asphalt wearing surfaces.

Due to the smooth surface of individual laminations and glued laminated decks, it is beneficial to provide a positive connection in order to ensure proper performance. The use of asphalt-impregnated geotextile fabric, when installed properly, has proven to be effective.

Asphalt wearing surfaces on stress-laminated wood decks have proven to perform well with only a tack coat and no reinforcement between the deck and the asphalt.

C9.9.8.3

Laminated decks may have offset laminations creating irregularities on the surface, and it is necessary to provide an adequate depth of wearing surface to provide proper protection to the wood deck. Chip seal wearing surfaces have a good record as applied to stress-laminated decks due to their behavior approaching that of solid slabs.

SECTION 10

FOUNDATIONS

Commentary is opposite the text it annotates.

10.1—SCOPE

Provisions of this Section shall apply for the design of spread footings, driven piles, drilled shaft, and micropile foundations.

The probabilistic LRFD basis of these Specifications, which produces an interrelated combination of load, load factor resistance, resistance factor, and statistical reliability, shall be considered when selecting procedures for calculating resistance other than that specified herein. Other methods, especially when locally recognized and considered suitable for regional conditions, may be used if resistance factors are developed in a manner that is consistent with the development of the resistance factors for the method(s) provided in these Specifications, and are approved by the Owner.

C10.1

The development of the resistance factors provided in this Section are summarized in Allen (2005), with additional details provided in Appendix A of Barker et al. (1991) and in Paikowsky et al. (2004).

The specification of methods of analysis and calculation of resistance for foundations herein is not intended to imply that field verification, reaction to conditions actually encountered in the field, or both are no longer needed. These traditional features of foundation design and construction are still practical considerations when designing in accordance with these Specifications.

10.2—DEFINITIONS

Battered Pile—A pile or micropile installed at an angle inclined to the vertical to provide higher resistance to lateral loads.

Bearing Pile—A pile or micropile whose purpose is to carry axial load through friction or point bearing.

Bent—A type of pier comprised of multiple columns or piles supporting a single cap and in some cases connected with bracing.

Bent Cap—A flexural substructure element supported by columns or piles that receives loads from the superstructure.

Bond Length—The length of a micropile that is bonded to the ground and which is conceptually used to transfer the applied axial loads to the surrounding soil or rock. Also known as the load transfer length.

BOR—Beginning of redrive.

Casing—Steel pipe introduced during the drilling process to temporarily stabilize the drill hole. Depending on the details of micropile construction and composition, this casing may be fully extracted during or after grouting, or may remain partially or completely in place as part of the final micropile pile configuration.

Centralizer—A device to centrally locate the core steel within a borehole.

Column Bent—A type of bent that uses two or more columns to support a cap. Columns may be drilled shafts or other independent units supported by individual footings or a combined footing; and may employ bracing or struts for lateral support above ground level.

Combination Point Bearing and Friction Pile—Pile that derives its capacity from contributions of both point bearing developed at the pile tip and resistance mobilized along the embedded shaft.

Combined Footing—A footing that supports more than one column.

Core Steel—Reinforcing bars or pipes used to strengthen or stiffen a micropile, excluding any left-in casing.

CD—Consolidated Drained.

CPT—Cone Penetration Test.

CU—Consolidated Undrained.

Deep Foundation—A foundation that derives its support by transferring loads to soil or rock at some depth below the structure by end bearing, adhesion or friction, or both.

DMT—Flat plate dilatometer test.

Drilled Shaft—A deep foundation unit, wholly or partly embedded in the ground, constructed by placing fresh concrete in a drilled hole with or without steel reinforcement. Drilled shafts derive their capacity from the surrounding soil and/or from the soil or rock strata below its tip. Drilled shafts are also commonly referred to as caissons, drilled caissons, bored piles, or drilled piers.

Effective Stress—The net stress across points of contact of soil particles, generally considered as equivalent to the total stress minus the pore water pressure.

EN—Engineering News.

EOD—End of driving.

ER—Hammer efficiency expressed as percent of theoretical free fall energy delivered by the hammer system actually used in a standard penetration test (SPT).

Free (Unbonded) Length—The designed length of a micropile that is not bonded to the surrounding ground or grout.

Friction Pile—A pile whose support capacity is derived principally from soil resistance mobilized along the side of the embedded pile.

Geomechanics Rock Mass Rating System—Rating system developed to characterize the engineering behavior of rock masses (Bieniawski, 1984).

Geotechnical Bond Strength—The nominal grout-to-ground bond strength.

GSI—Geological strength index.

IGM—Intermediate geomaterial, a material that is transitional between soil and rock in terms of strength and compressibility, such as residual soils, glacial tills, or very weak rock.

Isolated Footing—Individual support for the various parts of a substructure unit; the foundation is called a footing foundation.

Length of Foundation—Maximum plan dimension of a foundation element.

Load Test—Incremental loading of a foundation element, recording the total movement at each increment.

Micropile—A small-diameter drilled and grouted non-displacement pile (normally less than 12.0 in.) that is typically reinforced.

NSHM—National seismic hazard model.

OCR—Overconsolidation ratio; the ratio of the preconsolidation pressure to the current vertical effective stress.

Pile—A slender deep foundation unit, wholly or partly embedded in the ground, that is installed by driving, drilling, auguring, jetting, or otherwise and that derives its capacity from the surrounding soil from the soil or rock strata below its tip, or both.

Pile Bent—A type of bent using pile units, driven or placed, as the column members supporting a cap.

Pile Cap—A flexural substructure element located above or below the finished ground line that receives loads from substructure columns and is supported by shafts or piles.

Pile Shoe—A metal piece fixed to the penetration end of a pile to protect it from damage during driving and to facilitate penetration through very dense material.

Piping—Progressive erosion of soil by seeping water that produces an open pipe through the soil through which water flows in an uncontrolled and dangerous manner.

Plunge Length—The length of casing inserted into the bond zone to effect a transition between the upper cased portion to the lower uncased portion of a micropile.

Plunging—A mode of behavior observed in some pile load tests, wherein the settlement of the pile continues to increase with no increase in load.

PMT—Pressuremeter test.

Point-Bearing Pile—A pile whose support capacity is derived principally from the resistance of the foundation material on which the pile tip bears.

Post Grouting—The injection of additional grout into the load bond length of a micropile after the primary grout has set. Also known as regrouting or secondary grouting.

Primary Grout—Portland cement-based grout that is injected into a micropile hole, prior to or after the installation of the reinforcement to provide the load transfer to the surrounding ground along the micropile and afford a degree of corrosion protection for a micropile loaded in compression.

Reinforcement—The steel component of a micropile which accepts and/or resists applied loadings.

RMR—Rock mass rating.

RQD—Rock quality designation.

Shallow Foundation—A foundation that derives its support by transferring load directly to the soil or rock at shallow depth.

Slickensides—Polished and grooved surfaces in clayey soils or rocks resulting from shearing displacements along planes.

SPT—Standard penetration test.

Total Stress—Total pressure exerted in any direction by both soil and water.

UU—Unconsolidated undrained.

VST—Vane shear test (performed in the field).

Width of Foundation—Minimum plan dimension of a foundation element.

10.3—NOTATION

A	=	steel pile cross-sectional area (ft ²) (10.7.3.8.2)
A_b	=	cross-sectional area of steel reinforcing bar (in. ²) (10.9.3.10.2a) (10.9.3.10.2b) (10.9.3.10.3a) (10.9.3.10.3b)
A_c	=	cross-sectional area of steel casing (in. ²) (10.9.3.10.2a)
A_{ct}	=	cross-sectional area of steel casing considering reduction for threads (in. ²) (10.9.3.10.3a)
A_g	=	cross-sectional area of grout within micropile (in. ²) (10.9.3.10.2a) (10.9.3.10.2b)
A_p	=	area of pile, micropile, or shaft tip (ft ²) (10.7.3.8.6a) (10.8.3.5) (10.9.3.5.1)
A_s	=	design response spectral acceleration coefficient at a period of zero seconds; surface area of pile shaft; area of grout to ground bond surface of micropile through bond length (ft ²) (10.5.4.2) (10.7.3.8.6a) (10.8.3.5) (10.9.3.5.1)
A_u	=	uplift area of a belled drilled shaft (ft ²) (10.8.3.7.2)
a_{sl}	=	pile perimeter at the point considered (ft) (10.7.3.8.6g)
B	=	footing width; pile group width; pile diameter (ft) (10.6.2.4.3) (10.6.3.1.2a) (10.6.3.1.3) (10.7.2.3.2) (10.7.2.4) (10.7.3.8.2)
B_f	=	least width of footing (ft) (10.6.2.4.2c)
B'	=	effective footing width (ft) (10.6.1.3)
C	=	correction factor for concrete–soil interference (10.6.3.4)
C_c	=	compression index, void ratio definition (dim) (10.4.6.3)
C_{ce}	=	compression index, strain definition (dim) (10.6.2.4.3)
C_F	=	correction factor for K_s when δ is not equal to ϕ_f (dim) (10.7.3.8.6f)

C_N	=	overburden stress correction factor for N (dim) (10.4.6.2.4) (C10.5.4.2)
C_r	=	recompression index, void ratio definition (dim) (10.4.6.3) (10.6.2.4.3)
C_{re}	=	recompression index, strain definition (dim) (10.6.2.4.3)
C_{wp}, C_{wt}	=	correction factors for groundwater effect (dim) (10.6.3.1.2a) (10.6.3.1.3)
C_α	=	secondary compression index, void ratio definition (dim) (10.4.6.3) (10.6.2.4.3)
$C_{\alpha e}$	=	secondary compression index, strain definition (dim) (10.6.2.4.3)
C'	=	bearing capacity index (dim) (10.6.2.4.2b)
C_l	=	correction factor to incorporate the effect of strain relief due to embedment (10.6.2.4.2c)
C_2	=	correction factor to incorporate time-dependent (creep) increase in settlement for t (years) after construction (10.6.2.4.2c)
c	=	cohesion of soil, taken as undrained shear strength (ksf) (10.6.3.1.2a)
c_v	=	coefficient of consolidation (ft^2/yr) (10.4.6.3) (10.6.2.4.3)
c_1	=	undrained shear strength of the top layer of soil as depicted in Figure 10.6.3.1.2e-1 (ksf) (10.6.3.1.2e)
c_2	=	undrained shear strength of the lower layer of soil as depicted in Figure 10.6.3.1.2e-1 (ksf) (10.6.3.1.2e)
c'_1	=	drained shear strength of the top layer of soil in a two-layer system such as depicted in Figure 10.6.3.1.2e-1 (10.6.3.1.2f)
c^*	=	reduced effective stress soil cohesion for punching shear (ksf) (10.6.3.1.2b)
c'	=	effective stress cohesion intercept (ksf) (10.4.6.2.3)
D	=	disturbance factor; pile width or diameter; diameter of drilled shaft (ft); shaft diameter (ft) (10.4.6.4) (10.7.3.8.6g) (10.8.3.5.1c) (10.8.3.7.2)
D'	=	effective depth of pile or micropile group (ft) (10.7.2.3.2)
D_b	=	depth of penetration into bearing strata (ft) (10.7.2.3.2) (10.7.3.8.6g) (10.8.3.7.2)
D_f	=	footing embedment depth (ft) (10.6.3.1.2a) (10.6.3.1.3)
D_i	=	pile width or diameter at the point considered (ft) (10.7.3.8.6g)
D_p	=	diameter of the bell (ft) (10.8.3.7.2)
D_r	=	relative density of sand (C10.6.3.1.2b)
D_w	=	depth to water surface taken from the ground surface (ft) (10.6.3.1.2a)
d	=	pile diameter (A10.2)
d_b	=	grouted bond zone diameter (ft) (10.9.3.5.2) (10.9.3.10.4)
d_q	=	depth correction factor to account for the shearing resistance along the failure surface passing through cohesionless material above the bearing elevation (dim) (10.6.3.1.2a)
E	=	elastic modulus of layer i based on guidance provided in Table C10.4.6.3-1 or as specified in Table 10.6.2.4.2c-1; modulus of elasticity of pile material (ksi) (C10.4.6.3) (10.6.2.4.2c) (10.7.3.8.2)
E_d	=	developed hammer energy (ft-lb) (10.7.3.8.5)
E_m	=	rock mass modulus (ksi) (10.4.6.5)
E_p	=	modulus of elasticity of pile (ksi) (10.7.3.13.4)
E_R	=	intact modulus of a sample of rock core (10.4.6.5)
E_s	=	soil (Young's) modulus (ksi) (C10.4.6.3)
e	=	void ratio (dim) (10.6.2.4.3)
e_B	=	eccentricity of load parallel to the width of the footing (ft) (10.6.1.3)
e_L	=	eccentricity of load parallel to the length of the footing (ft) (10.6.1.3)
e_o	=	void ratio at initial vertical effective stress (dim) (10.6.2.4.3)
F_{co}	=	base resistance of wood in compression parallel to the grain (ksi) (10.7.8)
f'_c	=	28-day compressive strength of concrete or grout, unless another age is specified (ksi) (10.7.8) (10.9.3.10.2a) (10.9.3.10.2b)
f_{pe}	=	effective prestressing stress in concrete (ksi) (10.7.8)
f_s	=	approximate constant sleeve friction resistance measured from a CPT at depths below $8D$ (ksf) (C10.7.3.8.6g)
f_{si}	=	unit local sleeve friction resistance from CPT at the point considered (ksf) (10.7.3.8.6g)
f_y	=	specified minimum yield strength of steel (ksi) (10.7.8) (10.9.3.10.2a) (10.9.3.10.2b) (10.9.3.10.3a) (10.9.3.10.3b)
H	=	horizontal component of inclined loads (kips) (10.6.3.1.2a)
H_c	=	initial height of layer i (ft); height of compressible soil layer i (ft) (10.6.2.4.2b) (10.6.2.4.2c) (10.6.2.4.3)
H_{crit}	=	minimum distance below a spread footing to a second separate layer of soil with different properties that will affect shear strength of the foundation (ft) (10.6.3.1.2d)
H_d	=	length of longest drainage path in compressible soil layer (ft) (10.6.2.4.3)
H_s	=	height of sloping ground mass below bottom of footing (ft) (10.6.3.1.2c)
H_{s2}	=	distance from bottom of footing to top of the second soil layer (ft) (10.6.3.1.2e)
h_i	=	length interval at the point considered (ft) (10.7.3.8.6g)
I	=	influence factor of the effective group embedment (dim) (10.7.2.3.2)
I_p	=	influence coefficient to account for rigidity and dimensions of footing (dim) (10.6.2.4.4)

I_w	=	weak axis moment of inertia for a pile (ft ⁴) (C10.7.3.13.4)
I_z	=	strain influence factor from Figure 10.6.2.4.2c-1a (10.6.2.4.2c)
i_c, i_t, i_q	=	load inclination factors (dim) (10.6.3.1.2a)
K_c	=	correction factor for side friction in clay (dim) (10.7.3.8.6g)
K_s	=	correction factor for side friction in sand (dim) (10.7.3.8.6g)
K_δ	=	coefficient of lateral earth pressure at midpoint of soil layer under consideration (dim) (10.7.3.8.6f)
L	=	length of foundation; footing length; pile length (ft) (10.6.1.3) (10.6.3.1.2a) (10.7.3.8.2)
L_b	=	micropile bonded length (ft) (10.9.3.5.2)
L_f	=	length of footing (ft) (10.6.2.4.2c)
L_i	=	depth to middle of length interval at the point considered (ft) (10.7.3.8.6g)
L_p	=	micropile casing plunge length (ft) (10.9.3.10.4)
L'	=	effective footing length (ft) (10.6.1.3)
LL	=	liquid limit of soil (percent) (10.4.6.3)
m_b, s, a	=	fractured rock mass parameters (10.4.6.4)
N	=	uncorrected SPT blow count (blows/ft) (10.4.6.2.4)
N_{160}	=	average corrected SPT blow count along pile side (blows/ft) (10.7.3.8.6g)
N_1	=	SPT blow count corrected for overburden pressure σ'_v (blows/ft) (10.4.6.2.4)
N_{160}	=	SPT blow count corrected for both overburden and hammer efficiency effects (blows/ft) (10.4.6.2.4) (10.7.3.8.6g)
N_b	=	number of hammer blows for 1.0 in. of pile permanent set (blows/in.) (10.7.3.8.5)
N_c	=	cohesion term (undrained loading) bearing capacity factor (dim) (10.6.3.1.2a)
N_{cm}, N_{gm}	=	
N_{gm}	=	modified bearing capacity factors (dim) (10.6.3.1.2a)
N_m	=	modified bearing capacity factor (dim) (10.6.3.1.2e)
N_s	=	slope stability factor (dim) (10.6.3.1.2c)
N_q	=	surcharge (embedment) term (drained or undrained loading) bearing capacity factor (dim) (10.6.3.1.2a)
N_u	=	uplift adhesion factor for bell (dim) (10.8.3.7.2)
N_q^p	=	pile bearing capacity factor from Figure 10.7.3.8.6f-8 (dim) (10.7.3.8.6f)
N_γ	=	unit weight (footing width) term (drained loading) bearing capacity factor (dim) (10.6.3.1.2a)
N_1	=	number of intervals between the ground surface and a point $8D$ below the ground surface (dim) (10.7.3.8.6g)
N_2	=	number of intervals between $8D$ below the ground surface and the tip of the pile (dim) (10.7.3.8.6g)
N_{60}	=	SPT blow count corrected for hammer efficiency (blows/ft) (10.4.6.2.4) (10.8.3.5.2c)
n	=	number of soil layers within zone of stress influence of the footing (dim) (10.6.2.4.2b) (10.6.2.4.2c)
n_h	=	rate of increase of soil modulus with depth (ksi/ft) (C10.4.6.3) (C10.7.3.13.4)
PL	=	plastic limit of soil (percent) (10.4.6.3)
P_f	=	probability of failure (dim) (C10.5.5.2.1)
P_m	=	P -multipliers from Table 10.7.2.4-1 (dim) (10.7.2.4)
P_t	=	factored axial load transferred to the ground through the plunge length of the cased portion of a micropile (kips) (10.9.3.10.4)
P_u	=	factored axial load on uncased micropile segment adjusted for plunge length load transfer (kips) (10.9.3.10.4)
p_a	=	atmospheric pressure (ksf) (sea level value equivalent to 2.12 ksf or 1 atm or 14.7 psi) (10.8.3.5.1b) (10.8.3.5.2b)
p_o	=	effective in-situ overburden stress at the foundation depth (ksf) (10.6.2.4.2c)
p_{op}	=	effective in-situ overburden stress at the depth to peak strain influence factor, I_{zp} , as shown in Figure 10.6.2.4.2c-1b (ksf) (10.6.2.4.2c)
p_u	=	ultimate resistance for lateral loading (A10.2)
Q	=	load applied to top of footing, shaft, or micropile (kips); load test load (kips) (C10.6.3.1.2b) (10.7.3.8.2) (10.9.3.10.4)
Q_g	=	bearing capacity for block failure (kips) (C10.7.3.9)
q	=	net foundation pressure applied at $2D/3$; this pressure is equal to applied load at top of the group divided by the area of the equivalent footing and does not include the weight of the piles or the soil between the piles (ksf) (10.7.2.3.2)
q_c	=	static cone tip resistance (ksf) (C10.4.6.3) (10.7.2.3.2)
$\overline{q}_c$	=	average static cone tip resistance over a depth, B , below the equivalent footing (ksf) (10.6.3.1.3)
q_{c1}	=	average q_c over a distance of yD below the pile tip (path a-b-c) (ksf) (10.7.3.8.6g)
q_{c2}	=	average q_c over a distance of $8D$ above the pile tip (path c-e) (ksf) (10.7.3.8.6g)
q_L	=	limiting unit tip resistance from Figure 10.7.3.8.6f-9 (ksf) (10.7.3.8.6f)
q_t	=	limiting pile tip resistance (ksf) (10.7.3.8.6g)
q_n	=	nominal bearing resistance (ksf) (10.6.3.1.1)

$q_{n-sloping\ ground}$	= nominal bearing resistance of footings constructed on or adjacent to slopes (ksf) (10.6.3.1.2c)
q_o	= applied vertical stress at base of loaded area (ksf) (10.6.2.4.4)
q_p	= nominal unit tip resistance of pile or micropile (ksf) (10.7.3.8.6a) (10.7.3.8.6f) (10.7.3.8.6g) (10.9.3.5.1)
q_R	= factored bearing resistance (ksf) (10.6.3.1.1)
q_s	= unit shear resistance (ksf); unit side resistance of pile or micropile (ksf); unit grout-to-ground bond resistance (ksf) (10.6.3.4) (10.7.3.8.6a) (10.7.3.8.6g) (10.8.3.5) (10.9.3.5.1)
q_{sbell}	= nominal unit uplift resistance of a belled drilled shaft (ksf) (10.8.3.7.2)
q_u	= average unconfined compressive strength of rock core (ksf) (10.4.6.4)
q_1	= nominal bearing resistance of footing supported in the upper layer of a two-layer system, assuming the upper layer is infinitely thick (ksf) (10.6.3.1.2d)
q_2	= nominal bearing resistance of a fictitious footing of the same size and shape as the actual footing but supported on surface of the second (lower) layer of a two-layer system (ksf) (10.6.3.1.2d) (10.6.3.1.2f)
R_C	= factored structural resistance of a micropile to axial compression loading (kips) (10.9.3.10.2)
RC_{BC}	= reduction coefficient for bearing resistance of footings due to slope effects (dim) (10.6.3.1.2c)
R_{CC}	= factored structural axial compression resistance of cased micropile segments (kips) (10.9.3.10.2a)
R_{CU}	= factored structural axial compression resistance of uncased micropile segments (kips) (10.9.3.10.2b)
R_{ep}	= nominal passive resistance of soil available throughout the design life of the structure (kips) (10.6.3.4)
R_n	= nominal resistance of footing, pile, shaft, or micropile (kips) (10.6.3.4) (C10.7.3.3) (10.9.3.5.1) (10.9.3.10.2) (10.9.3.10.3)
R_{ndr}	= nominal pile driving resistance (kips) (C10.7.3.3) (10.7.3.6) (10.7.3.8.5)
R_{restat}	= predicted nominal resistance of pile from static analysis method (kips) (C10.7.3.3)
R_p	= nominal pile or micropile tip resistance (kips) (10.7.3.8.6a) (10.8.3.5) (10.9.3.5.1)
R_R	= factored nominal resistance of a footing, pile, micropile, or shaft (kips) (10.6.3.4) (10.7.3.8.6a) (10.8.3.5) (10.8.3.7.2) (10.9.3.5.1)
R_s	= pile side resistance (kips); nominal uplift resistance due to side resistance (kips); nominal micropile grout-to-ground bond resistance (kips) (10.7.3.8.6a) (10.7.3.10) (10.8.3.5) (10.9.3.5.1)
R_{sbell}	= nominal uplift resistance of a belled drilled shaft (kips) (10.8.3.7.2)
R_T	= factored structural axial tension resistance (kips) (10.9.3.10.3)
R_{TC}	= factored structural axial tension resistance of cased micropile segments (kips) (10.9.3.10.3a)
R_{TU}	= factored structural axial tension resistance of uncased micropile segments (kips) (10.9.3.10.3b)
R_{ug}	= nominal uplift resistance of a pile group (kips) (10.7.3.11)
R_τ	= nominal sliding resistance between the footing and the soil (kips) (10.6.3.4)
r	= radius of circular footing or $B/2$ for square footing (ft) (10.6.2.4.4)
S_c	= primary consolidation settlement (ft) (10.6.2.4.1)
$S_{c(1-D)}$	= single dimensional consolidation settlement (ft) (10.6.2.4.3)
S_e	= elastic (or immediate) settlement (ft) (10.6.2.4.1)
S_i	= elastic (or immediate) settlement based on Schmertmann method (ft) (10.6.2.4.2c)
S_s	= secondary settlement (ft) (10.6.2.4.1)
S_t	= total settlement (ft) (10.6.2.4.1)
S_u	= undrained shear strength (ksf) (10.4.6.2.2) (10.6.3.4) (10.7.3.8.6b) (10.7.3.8.6e) (C10.7.3.9) (C10.7.3.13.4) (10.8.3.5.1b) (10.8.3.5.1c) (C10.8.3.7.2)
$\bar{S}_u$	= average undrained shear strength along pile side (ksf) (C10.7.3.9) (10.7.3.11)
s	= pile permanent set (in.) (10.7.3.8.5)
s_c, s_f, s_g	= shape correction factors (dim) (10.6.3.1.2a)
s_f	= pile top movement during load test (in.) (10.7.3.8.2)
T	= time factor (dim) (10.6.2.4.3)
t	= time from completion of construction to date under consideration for evaluation of C_2 (years); time for a given percentage of one-dimensional consolidation settlement to occur (years) (10.6.2.4.2c) (10.6.2.4.3)
t_1, t_2	= arbitrary time intervals for determination of secondary settlement, S_s (years) (10.6.2.4.3)
V	= unfactored vertical load; pile displacement volume (ft ³ /ft) (10.6.3.1.2a) (10.6.3.4) (10.7.3.8.6f)
ν	= Poisson's ratio (C10.4.6.3) (C10.4.6.5) (10.6.2.4.4)
W_g	= weight of block of soil, piles and pile cap (kips) (10.7.3.11)
X	= a factor used to determine the value of elastic modulus; width or smallest dimension of pile group (ft) (10.6.2.4.2c) (C10.7.3.8.2) (10.7.3.11)
Y	= length of pile group (ft) (10.7.3.11)
y_u	= pile deflections (A10.2)
Z	= total embedded pile length; depth of the block of soil below pile cap taken from Figure 10.7.3.11-2; penetration of shaft (ft) (C10.7.3.8.6g) (10.7.3.11) (10.8.3.5.1c)

z	=	depth below the ground surface (ft) (C10.4.6.3)
α	=	adhesion factor applied to S_u (dim) (10.7.3.8.6b)
α_b	=	nominal micropile grout-to-ground bond stress (ksf) (10.9.3.5.2) (10.9.3.10.4)
α_E	=	reduction factor to account for jointing in rock (dim) (10.8.3.5.4b)
α_t	=	coefficient from Figure 10.7.3.8.6f-7 (dim) (10.7.3.8.6f)
β	=	reliability index; coefficient relating the vertical effective stress and the unit skin friction of a pile or drilled shaft; load transfer coefficient (dim) (C10.5.5.2.1) (10.7.3.8.6c) (10.8.3.5.2b)
β_m	=	punching index (dim) (10.6.3.1.2e)
β_z	=	factor to account for footing shape and rigidity (dim) (10.6.2.4.4)
γ	=	unit density of soil (kcf) (10.6.3.1.2c)
γ_f	=	total (moist) unit weight of soil below the bearing depth of the footing (kcf) (10.6.3.1.2a)
γ_g	=	total (moist) unit weight of soil above the bearing depth of the footing (kcf) (10.6.3.1.2a)
γ_{SE}	=	load factor for settlement (C10.5.2.2.2) (C10.6.2.4.2b)
ΔH_i	=	elastic settlement of layer i (ft) (10.6.2.4.2b)
ΔJ_i	=	elastic spring stiffness of layer i (ft/ksf) (10.6.2.4.2c)
Δp	=	net uniform applied stress (load intensity) at the foundation depth as shown in Figure 10.6.2.4.2c-1b, in which p is equal to the uniform applied footing stress, σ_v , as specified in Article 11.6.3.2 (ksf) (10.6.2.4.2c)
δ	=	elastic deformation of pile (in.); friction angle between foundation and soil (degrees) (C10.7.3.8.2) (10.7.3.8.6f)
ϵ_v	=	vertical strain of over consolidated soil (in./in.) (10.6.2.4.3)
η	=	shaft efficiency reduction factor for axial resistance of a drilled shaft or micropile group (dim) (10.7.3.9)
θ	=	projected direction of load in the plane of the footing, measured from the side of length L (degrees) (10.6.3.1.2a)
λ	=	empirical coefficient relating the passive lateral earth pressure and the unit skin friction of a pile (dim) (10.7.3.8.6d)
μ_c	=	reduction factor for consolidation settlements to account for three-dimensional effects (dim) (10.6.2.4.3)
σ'_p	=	maximum past vertical effective stress in soil at midpoint of soil layer under consideration (ksf) (10.6.2.4.3)
σ'_o	=	initial vertical effective stress in soil at midpoint of soil layer under consideration (ksf) (10.6.2.4.3)
ϕ_f	=	angle of internal friction of drained soil (degrees) (10.4.6.2.4)
ϕ'_f	=	drained (long term) effective angle of internal friction of clays (degrees) (10.4.6.2.3)
ϕ'_1	=	effective stress angle of internal friction of the top layer of soil (degrees) (10.6.3.1.2f)
ϕ'_s	=	secant friction angle (degrees) (10.4.6.2.4)
ϕ^*	=	reduced effective stress soil friction angle for punching shear (degrees) (10.6.3.1.2b)
φ	=	resistance factor (dim) (10.5.5.2.3) (10.6.3.4) (10.9.3.5.1)
φ_b	=	resistance factor for bearing of shallow foundations (dim) (10.5.5.2.2)
φ_{bl}	=	resistance factor for driven piles or shafts, block failure in clay (dim) (10.5.5.2.3)
φ_C	=	structural resistance factor for micropiles in axial compression (dim) (10.9.3.10.2)
φ_{CC}	=	structural resistance factor for cased micropiles segments in axial compression (dim) (10.5.5.2.5) (10.9.3.10.2a)
φ_{CU}	=	structural resistance factor for uncased micropiles segments in axial compression (dim) (10.5.5.2.5) (10.9.3.10.2b)
φ_{da}	=	resistance factor for driven piles, drivability analysis (dim) (10.5.5.2.3)
φ_{dyn}	=	resistance factor for driven piles, dynamic analysis and static load test methods (dim) (10.5.5.2.3) (C10.7.3.7)
φ_{ep}	=	resistance factor for passive soil resistance (dim) (10.5.5.2.2)
φ_{load}	=	resistance factor for shafts, static load test (dim) (10.5.5.2.4)
φ_{qp}	=	resistance factor for tip resistance (dim) (10.8.3.5) (10.9.3.5.1)
φ_{qs}	=	resistance factor for shaft side resistance (dim) (10.8.3.5) (10.9.3.5.1)
φ_{stat}	=	resistance factor for driven piles or shafts, static analysis methods (dim) (10.5.5.2.3) (10.5.5.2.4)
φ_T	=	structural resistance factor for micropiles in axial tension (dim) (10.9.3.10.3)
φ_{TC}	=	structural resistance factor for cased micropiles segments in axial tension (dim) (10.5.5.2.5) (10.9.3.10.3a)
φ_{TU}	=	structural resistance factor for uncased micropiles segments in axial tension (dim) (10.5.5.2.5) (10.9.3.10.3b)
φ_{ug}	=	resistance factor for group uplift (dim) (10.5.5.2.3) (10.5.5.2.4)
φ_{up}	=	resistance factor for uplift resistance of a single pile or drilled shaft (dim) (10.5.5.2.3) (10.5.5.2.4)
φ_{upload}	=	resistance factor for shafts, static uplift load test (dim) (10.5.5.2.4) (10.9.3.5.1)
φ_τ	=	resistance factor for sliding resistance between soil and footing (dim) (10.5.5.2.2)

10.4—SOIL AND ROCK PROPERTIES

10.4.1—Informational Needs

The expected project requirements shall be analyzed to determine the type and quantity of information to be developed during the geotechnical exploration. This analysis should consist of the following:

- Identifying design and constructability requirements, e.g., provide grade separation, support loads from bridge superstructure, provide for dry excavation, and their effect on the geotechnical information needed.
- Identifying performance criteria, e.g., limiting settlements, right of way restrictions, proximity of adjacent structures, and schedule constraints.
- Identifying areas of geologic concern on the site and potential variability of local geology.
- Identifying areas of hydrologic concern on the site, e.g., potential erosion or scour locations.
- Developing likely sequence and phases of construction and their effect on the geotechnical information needed.
- Identifying engineering analyses to be performed, e.g., bearing capacity, settlement, global stability.
- Identifying engineering properties and parameters required for these analyses.
- Determining methods to obtain parameters and assess the validity of such methods for the material type and construction methods.
- Determining the number of tests/samples needed and appropriate locations for them.

10.4.2—Subsurface Exploration

Subsurface explorations shall be performed to provide the information needed for the design and construction of foundations. The extent of exploration shall be based on variability in the subsurface conditions, structure type, and any project requirements that may affect the foundation design or construction. The exploration program should be extensive enough to reveal the nature and types of soil deposits and/or rock formations encountered, the engineering properties of the soils and/or rocks, the potential for liquefaction, and the groundwater conditions. The exploration program should be sufficient to identify and delineate problematic subsurface conditions such as karstic formations, mined out areas, swelling/collapsing soils, existing fill or waste areas, and so forth.

Borings should be sufficient in number and depth to establish a reliable longitudinal and transverse substrata profile at areas of concern such as at structure foundation locations and adjacent earthwork locations, and to investigate any adjacent geologic hazards that could affect the structure performance.

C10.4.1

The first phase of an exploration and testing program requires that the Engineer understand the project requirements and the site conditions and/or restrictions. The ultimate goal of this phase is to identify geotechnical data needs for the project and potential methods available to assess these needs.

Geotechnical Engineering Circular #5—Evaluation of Soil and Rock Properties (Sabatini et al., 2002) provides a summary of information needs and testing considerations for various geotechnical applications.

C10.4.2

The performance of a subsurface exploration program is part of the process of obtaining information relevant for the design and construction of substructure elements. The elements of the process that should precede the actual exploration program include a search and review of published and unpublished information at and near the site, a visual site inspection, and design of the subsurface exploration program. Refer to Mayne et al. (2001) and Sabatini et al. (2002) for guidance regarding the planning and conduct of subsurface exploration programs.

The suggested minimum number and depth of borings are provided in Table 10.4.2-1. While engineering judgment will need to be applied by a licensed and experienced geotechnical professional to adapt the exploration program to the foundation types and depths needed and to the variability in the subsurface conditions observed, the intent of Table 10.4.2-1 regarding the minimum level of exploration needed should be carried out. The depth of borings indicated in Table 10.4.2-1 performed before or during design should take into account the potential for changes in the type, size and depth of the planned foundation elements.

As a minimum, the subsurface exploration and testing program shall obtain information adequate to analyze foundation stability and settlement with respect to:

- geological formation(s) present;
- location and thickness of soil and rock units;
- engineering properties of soil and rock units, e.g., unit weight, shear strength and compressibility;
- groundwater conditions;
- ground surface topography; and
- local considerations, e.g., liquefiable, expansive or dispersive soil deposits, underground voids from solution weathering or mining activity, or slope instability potential.

Table 10.4.2-1 shall be used as a starting point for determining the locations of borings. The final exploration program should be adjusted based on the variability of the anticipated subsurface conditions as well as the variability observed during the exploration program. If conditions are determined to be variable, the exploration program should be increased relative to the requirements in Table 10.4.2-1 such that the objective of establishing a reliable longitudinal and transverse substrata profile is achieved. If conditions are observed to be homogeneous or otherwise are likely to have minimal impact on the foundation performance, and previous local geotechnical and construction experience has indicated that subsurface conditions are homogeneous or otherwise are likely to have minimal impact on the foundation performance, a reduced exploration program relative to what is specified in Table 10.4.2-1 may be considered.

If requested by the Owner or as required by law, boring and penetration test holes shall be plugged.

Laboratory tests, in-situ tests, or both shall be performed to determine the strength, deformation, and permeability characteristics of soils and/or rocks and their suitability for the foundation proposed.

Table 10.4.2-1 should be used only as a first step in estimating the number of borings for a particular design, as actual boring spacings will depend upon the project type and geologic environment. In areas underlain by heterogeneous soil deposits and/or rock formations, it will probably be necessary to drill more frequently and/or deeper than the minimum guidelines in Table 10.4.2-1 to capture variations in soil and/or rock type and to assess consistency across the site area. For situations where large diameter rock socketed shafts will be used or where drilled shafts are being installed in formations known to have large boulders, or voids such as in karstic or mined areas, it may be necessary to advance a boring at the location of each shaft. Even the best and most detailed subsurface exploration programs may not identify every important subsurface problem condition if conditions are highly variable. The goal of the subsurface exploration program, however, is to reduce the risk of such problems to an acceptable minimum.

In a laterally homogeneous area, drilling or advancing a large number of borings may be redundant, since each sample tested would exhibit similar engineering properties. Furthermore, in areas where soil or rock conditions are known to be very favorable to the construction and performance of the foundation type likely to be used, e.g., footings on very dense soil, and groundwater is deep enough to not be a factor, obtaining fewer borings than provided in Table 10.4.2-1 may be justified. In all cases, it is necessary to understand how the design and construction of the geotechnical feature will be affected by the soil and/or rock mass conditions in order to optimize the exploration.

Borings may need to be plugged due to requirements by regulatory agencies having jurisdiction and/or to prevent water contamination and/or surface hazards.

Parameters derived from field tests, e.g., driven pile resistance based on cone penetrometer testing, may also be used directly in design calculations based on empirical relationships. These are sometimes found to be more reliable than analytical calculations, especially in familiar ground conditions for which the empirical relationships are well-established.

Table 10.4.2-1—Minimum Number of Exploration Points and Depth of Exploration (modified after Sabatini et al., 2002)

Application	Minimum Number of Exploration Points and Location of Exploration Points	Minimum Depth of Exploration
Retaining Walls	A minimum of one exploration point for each retaining wall. For retaining walls more than 100 ft in length, exploration points spaced every 100 to 200 ft with locations alternating from in front of the wall to behind the wall. For anchored walls, additional exploration points in the anchorage zone spaced at 100 to 200 ft. For soil-nailed walls, additional exploration points at a distance of 1.0 to 1.5 times the height of the wall behind the wall spaced at 100 to 200 ft.	Investigate to a depth below bottom of wall at least to a depth where stress increase due to estimated foundation load is less than ten percent of the existing effective overburden stress at that depth and between one and two times the wall height. Exploration depth should be great enough to fully penetrate soft highly compressible soils, e.g., peat, organic silt, or soft fine-grained soils, into competent material of suitable bearing capacity, e.g., stiff to hard cohesive soil, compact dense cohesionless soil, or bedrock.
Shallow Foundations	For substructure, e.g., piers or abutments, widths less than or equal to 100 ft, a minimum of one exploration point per substructure. For substructure widths greater than 100 ft, a minimum of two exploration points per substructure. Additional exploration points should be provided if erratic subsurface conditions are encountered.	Depth of exploration should be: • great enough to fully penetrate unsuitable foundation soils, e.g., peat, organic silt, or soft fine-grained soils, into competent material of suitable bearing resistance, e.g., stiff to hard cohesive soil, or compact to dense cohesionless soil or bedrock; • at least to a depth where stress increase due to estimated foundation load is less than ten percent of the existing effective overburden stress at that depth; and • if bedrock is encountered before the depth required by the second criterion above is achieved, exploration depth should be great enough to penetrate a minimum of 10 ft into the bedrock, but rock exploration should be sufficient to characterize compressibility of infill material of near-horizontal to horizontal discontinuities. Note that for highly variable bedrock conditions, or in areas where very large boulders are likely, more than 10 ft or rock core may be required to verify that adequate quality bedrock is present.
Deep Foundations	For substructure, e.g., bridge piers or abutments, widths less than or equal to 100 ft, a minimum of one exploration point per substructure. For substructure widths greater than 100 ft, a minimum of two exploration points per substructure. Additional exploration points should be provided if erratic subsurface conditions are encountered, especially for the case of shafts socketed into bedrock. To reduce design and construction risk due to subsurface condition variability and the potential for construction claims, at least one exploration per shaft should be considered for large diameter shafts (e.g., greater than 5 ft in diameter), especially when shafts are socketed into bedrock.	In soil, depth of exploration should extend below the anticipated pile or shaft tip elevation a minimum of 20 ft, or a minimum of two times the minimum pile group dimension, whichever is deeper. All borings should extend through unsuitable strata such as unconsolidated fill, peat, highly organic materials, soft fine-grained soils, and loose coarse-grained soils to reach hard or dense materials. For piles bearing on rock, a minimum of 10 ft of rock core shall be obtained at each exploration point location to verify that the boring has not terminated on a boulder. For shafts supported on or extending into rock, a minimum of 10 ft of rock core, or a length of rock core equal to at least three times the shaft diameter for isolated shafts or two times the minimum shaft group dimension, whichever is greater, shall be extended below the anticipated shaft tip elevation to determine the physical characteristics of rock within the zone of foundation influence. Note that for highly variable bedrock conditions, or in areas where very large boulders are likely, more than 10 ft or rock core may be required to verify that adequate quality bedrock is present.

10.4.5—Geophysical Tests

Geophysical testing should be used only in combination with information from direct methods of exploration, such as SPT, CPT, or other direct methods of exploration approved by the Owner, to establish:

- stratification of the subsurface materials,
- the profile of the top of bedrock and bedrock quality,
- dynamic properties of material making up the geologic profile,
- depth to groundwater,
- limits of types of soil deposits,
- the presence of voids,
- anomalous deposits,
- buried pipes, and
- depths of existing foundations.

Geophysical tests shall be selected and conducted in accordance with available ASTM standards. For those cases where ASTM standards are not available, other widely-accepted detailed guidelines, such as Sabatini et al. (2002), AASHTO *Manual on Subsurface Investigations* (2022), Arman et al. (1997) and Campanella (1994), should be used.

C10.4.5

Geophysical testing offers some notable advantages and some disadvantages that should be considered before the technique is recommended for a specific application. The advantages are summarized as follows:

- Many geophysical tests are noninvasive and thus, offer, significant benefits in cases where conventional drilling, testing and sampling are difficult, e.g., deposits of gravel, talus deposits, or where potentially contaminated subsurface soils may occur.
- In general, geophysical testing covers a relatively large area, thus providing the opportunity to generally characterize large areas in order to optimize the locations and types of in-situ testing and sampling. Geophysical methods are particularly well suited to projects that have large longitudinal extent compared to lateral extent, e.g., new highway construction.
- Geophysical measurement assesses the characteristics of soil and rock at very small strains, typically on the order of 0.001 percent, thus providing information on truly elastic properties, which are used to evaluate service limit states, as well as properties for evaluating the seismic response of the soil or rock.
- For the purpose of obtaining subsurface information, geophysical methods are relatively inexpensive when considering cost relative to the large areas over which information can be obtained.

Some of the disadvantages of geophysical methods include:

- Most methods work best for situations in which there is a large difference in stiffness or conductivity between adjacent subsurface units.
- It is difficult to develop good stratigraphic profiling if the general stratigraphy consists of hard material over soft material or resistive material over conductive material.
- Results are generally interpreted qualitatively and, therefore, only an experienced engineer or geologist familiar with the particular testing method can obtain useful results.
- Specialized equipment is required (compared to more conventional subsurface exploration tools).
- Since evaluation is performed at very low strains, or no strain at all, information regarding ultimate strength for evaluation of strength limit states is only obtained by correlation.

10.4.6—Selection of Design Properties

10.4.6.1—General

Subsurface soil or rock properties shall be determined using one or more of the following methods:

- in-situ testing during the field exploration program, including consideration of any geophysical testing conducted;
- laboratory testing; and
- back analysis of design parameters based on site performance data.

Local experience, local geologic formation specific property correlations, and knowledge of local geology, in addition to broader-based experience and relevant published data, should also be considered in the final selection of design parameters. If published correlations are used in combination with one of the methods listed above, the applicability of the correlation to the specific geologic formation shall be considered through the use of local experience, local test results, and/or long-term experience.

The focus of geotechnical design property assessment and final selection shall be on the individual geologic strata identified at the project site.

The design values selected for the parameters should be appropriate to the particular limit state and its correspondent calculation model under consideration.

The determination of design parameters for rock shall take into consideration that rock mass properties are generally controlled by the discontinuities within the rock mass and not the properties of the intact material. Therefore, engineering properties for rock should account for the properties of the intact pieces and for the properties of the rock mass as a whole, specifically considering the discontinuities within the rock mass. A combination of laboratory testing of small samples, empirical analysis, and field observations should be employed to determine the engineering properties of rock masses, with greater emphasis placed on visual observations and quantitative descriptions of the rock mass.

There are a number of different geophysical in-situ tests that can be used for stratigraphic information and determination of engineering properties. These methods can be combined with each other and/or combined with the in-situ tests presented in Article 10.4.4 to provide additional resolution and accuracy. ASTM D6429, provides additional guidance on selection of suitable methods.

C10.4.6.1

A geologic stratum is characterized as having the same geologic depositional history and stress history, and generally has similarities throughout the stratum in terms of density, source material, stress history, and hydrogeology. The properties of a given geologic stratum at a project site are likely to vary significantly from point to point within the stratum. In some cases, a measured property value may be closer in magnitude to the measured property value in an adjacent geologic stratum than to the measured properties at another point within the same stratum. However, soil and rock properties for design should not be averaged across multiple strata.

It should also be recognized that some properties, e.g., undrained shear strength in normally consolidated clays, may vary as a predictable function of a stratum dimension, e.g., depth below the top of the stratum. Where the property within the stratum varies in this manner, the design parameters should be developed taking this variation into account, which may result in multiple values of the property within the stratum as a function of a stratum dimension such as depth.

The observational method, or use of back analysis, to determine engineering properties of soil or rock is often used with slope failures, embankment settlement or excessive settlement of existing structures. With landslides or slope failures, the process generally starts with determining the geometry of the failure and then determining the soil/rock parameters or subsurface conditions that result from a combination of load and resistance factors that approach 1.0. Often the determination of the properties is aided by correlations with index tests or experience on other projects. For embankment settlement, a range of soil properties is generally determined based on laboratory performance testing on undisturbed samples. Monitoring of fill settlement and pore pressure in the soil during construction allows the soil properties and prediction of the rate of future settlement to be refined. For structures such as bridges that experience unacceptable settlement or retaining walls that have excessive deflection, the engineering properties of the soils can sometimes be determined if the magnitudes of the loads are known. As with slope stability analysis, the subsurface stratigraphy must be adequately known, including the history of the groundwater level at the site.

Local geologic formation-specific correlations may be used if well-established by data comparing the

prediction from the correlation to measured high quality laboratory performance data, or back-analysis from full scale performance of geotechnical elements affected by the geologic formation in question.

The Engineer should assess the variability of relevant data to determine if the observed variability is a result of inherent variability of subsurface materials and testing methods or if the variability is a result of significant variations across the site. Methods to compare soil parameter variability for a particular project to published values of variability based on database information of common soil parameters are presented in Sabatini et al. (2002) and Duncan (2000). Where the variability is deemed to exceed the inherent variability of the material and testing methods, or where sufficient relevant data is not available to determine an average value and variability, the Engineer may perform a sensitivity analysis using average parameters and a parameter reduced by one standard deviation, i.e., “mean minus one sigma,” or a lower bound value. By conducting analyses at these two potential values, an assessment is made of the sensitivity of the analysis results to a range of potential design values. If these analyses indicate that acceptable results are provided and that the analyses are not particularly sensitive to the selected parameters, the Engineer may be comfortable with concluding the analyses. If, on the other hand, the Engineer determines that the calculation results are marginal or that the results are sensitive to the selected parameter, additional data collection/review and parameter selection are warranted.

When evaluating service limit states, it is often appropriate to determine both upper and lower bound values from the relevant data, since the difference in displacement of substructure units is often more critical to overall performance than the actual value of the displacement for the individual substructure unit.

For strength limit states, average measured values of relevant laboratory test data, in-situ test data, or both were used to calibrate the resistance factors provided in Article 10.5, at least for those resistance factors developed using reliability theory, rather than a lower bound value. It should be recognized that to be consistent with how the resistance factors presented in Article 10.5.5.2 were calibrated, i.e., to average property values, accounting for the typical variability in the property, average property values for a given geologic unit should be selected. However, depending on the availability of soil or rock property data and the variability of the geologic strata under consideration, it may not be possible to reliably estimate the average value of the properties needed for design. In such cases, the Engineer may have no choice but to use a more conservative selection of design parameters to mitigate the additional risks created by potential variability or the paucity of relevant data. Note that for those resistance factors that were determined based on calibration by fitting to ASD, this property selection issue is not relevant, and property selection should be based on past practice.

10.4.6.2—Soil Strength

10.4.6.2.1—General

The selection of soil shear strength for design should consider, at a minimum, the following:

- the rate of construction loading relative to the hydraulic conductivity of the soil, i.e., drained or undrained strengths;
- the effect of applied load direction on the measured shear strengths during testing;
- the effect of expected levels of deformation for the geotechnical structure; and
- the effect of the construction sequence.

10.4.6.2.2—Undrained Strength of Cohesive Soils

Where possible, laboratory consolidated undrained (CU) and unconsolidated undrained (UU) testing should be used to estimate the undrained shear strength, S_u , supplemented as needed with values determined from in-situ testing. Where collection of undisturbed samples for laboratory testing is difficult, values obtained from in-situ testing methods may be used. For relatively thick deposits of cohesive soil, profiles of S_u as a function of depth should be obtained so that the deposit stress history and properties can be ascertained.

C10.4.6.2.1

Refer to Sabatini et al. (2002) for additional guidance on determining which soil strength parameters are appropriate for evaluating a particular soil type and loading condition. In general, where loading is rapid enough and/or the hydraulic conductivity of the soil is low enough such that excess pore pressure induced by the loading does not dissipate, undrained (total) stress parameters should be used. Where loading is slow enough and/or the hydraulic conductivity of the soil is great enough such that excess pore pressures induced by the applied load dissipate as the load is applied, drained (effective) soil parameters should be used. Drained (effective) soil parameters should also be used to evaluate long term conditions where excess pore pressures have been allowed to dissipate or where the designer has explicit knowledge of the expected magnitude and distribution of the excess pore pressure.

C10.4.6.2.2

For design analyses of short-term conditions in normally to lightly overconsolidated cohesive soils, the undrained shear strength, S_u , is commonly evaluated. Since undrained strength is not a unique property, profiles of undrained strength developed using different testing methods will vary. Typical transportation project practice entails determination of S_u based on laboratory CU and UU testing and, for cases where undisturbed sampling is very difficult, field vane testing. Other in-situ methods can also be used to estimate the value of S_u .

Specific issues that should be considered when estimating the undrained shear strength are described below:

- Strength measurements from hand torvanes, pocket penetrometers, or unconfined compression tests should not be solely used to evaluate undrained shear strength for design analyses. CU triaxial tests and in-situ tests should be used.
- For relatively deep deposits of cohesive soil, e.g., approximately 20.0 ft depth or more, all available undrained strength data should be plotted with depth. The type of test used to evaluate each undrained strength value should be clearly identified. Known soil layering should be used so that trends in undrained strength data can be developed for each soil layer.
- Review data summaries for each laboratory strength test method. Moisture contents of specimens for strength testing should be compared to moisture contents of other samples at similar depths. Significant changes in moisture content will affect measured undrained strengths. Review boring logs, Atterberg limits, grain size, and unit weight measurements to confirm soil layering.

- CU tests on normally to slightly over consolidated samples that exhibit disturbance should contain at least one specimen consolidated to at least $4\sigma_p'$ to permit extrapolation of the undrained shear strength at σ_p' .
- Undrained strengths from CU tests correspond to the effective consolidation pressure used in the test. This effective stress needs to be converted to the equivalent depth in the ground.
- A profile of σ_p' (or OCR) should be developed and used in evaluating undrained shear strength.
- Correlations for S_u based on in-situ test measurements should not be used for final design unless they have been calibrated to the specific soil profile under consideration. Correlations for S_u based on SPT should be avoided.

10.4.6.2.3—Drained Strength of Cohesive Soils

Long-term effective stress strength parameters, c' and ϕ'_s , of clays should be evaluated by slow consolidated drained direct shear box tests, consolidated drained (CD) triaxial tests, or CU triaxial tests with pore pressure measurements. In laboratory tests, the rate of shearing should be sufficiently slow to ensure substantially complete dissipation of excess pore pressure in the drained tests or, in undrained tests, complete equalization of pore pressure throughout the specimen.

C10.4.6.2.3

The selection of peak, fully softened, or residual strength for design analyses should be based on a review of the expected or tolerable displacements of the soil mass.

The use of a nonzero cohesion intercept, c' , for long-term analyses in natural materials must be carefully assessed. With continuing displacements, it is likely that the cohesion intercept value will decrease to zero for long-term conditions, especially for highly plastic clays.

10.4.6.2.4—Drained Strength of Granular Soils

The drained friction angle of granular deposits should be evaluated by correlation to the results of SPT, CPT, or other relevant in-situ tests. Laboratory shear strength tests on undisturbed samples, if feasible to obtain, or reconstituted disturbed samples, may also be used to determine the shear strength of granular soils.

If SPT N values are used, unless otherwise specified for the design method or correlation being used, they shall be corrected for the effects of overburden pressure determined as:

$$N_1 = C_N N \quad (10.4.6.2.4-1)$$

N_1 = SPT blow count corrected for overburden pressure, σ'_v (blows/ft)

C_N = $[0.77 \log_{10}(40/\sigma'_v)]$, and $C_N < 2.0$

σ'_v = vertical effective stress (ksf)

N = uncorrected SPT blow count (blows/ft)

C10.4.6.2.4

Because obtaining undisturbed samples of granular deposits for laboratory testing is extremely difficult, the results of in-situ tests are commonly used to develop estimates of the drained friction angle, ϕ_f . If reconstituted disturbed soil samples and laboratory tests are used to estimate the drained friction angle, the reconstituted samples should be compacted to the same relative density estimated from the available in-situ data. The test specimen should be large enough to allow the full grain size range of the soil to be included in the specimen. This may not always be possible, and if not possible, it should be recognized that the shear strength measured would likely be conservative.

A method using the results of SPT is presented. Other in-situ tests, such as CPT and flat plate dilatometer tests (DMT), may be used. For details on determination of ϕ_f from these tests, refer to Sabatini et al. (2002).

SPT N values should also be corrected for hammer efficiency, if applicable to the design method or correlation being used, determined as:

$$N_{60} = \left(\frac{ER}{60\%} \right) N \quad (10.4.6.2.4-2)$$

The use of automatic trip hammers is increasing. In order to use correlations based on standard rope and cathead hammers, the SPT N values must be corrected to reflect the greater energy delivered to the sampler by these systems.

Hammer efficiency, ER , for specific hammer systems used in local practice may be used in lieu of the

where:

- N_{60} = SPT blow count corrected for hammer efficiency (blows/ft)
 ER = hammer efficiency expressed as percent of theoretical free fall energy delivered by the hammer system actually used (dim)
 N = uncorrected SPT blow count (blows/ft)

When SPT blow counts have been corrected for both overburden effects and hammer efficiency effects, the resulting corrected blow count shall be denoted as N_{160} , determined as:

$$N_{160} = C_N N_{60} \quad (10.4.6.2.4-3)$$

The drained friction angle of granular deposits should be determined based on the following correlation.

Table 10.4.6.2.4-1—Correlation of SPT N_{160} Values to Drained Friction Angle of Granular Soils (modified after Bowles, 1977)

N_{160}	ϕ_f
<4	25–30
4	27–32
10	30–35
30	35–40
50	38–43

For gravels and rock fill materials where SPT is not reliable, Figure 10.4.6.2.4-1 should be used to estimate the drained friction angle.

Rock Fill Grade	Particle Unconfined Compressive Strength (ksf)
A	>4,610
B	3,460–4,610
C	2,590–3,460
D	1,730–2,590
E	≤1,730

values provided. If used, specific hammer system efficiencies shall be developed in general accordance with ASTM D4945 for dynamic analysis of driven piles or other accepted procedure.

The following values for ER may be assumed if hammer specific data are not available, e.g., from older boring logs:

- ER = 60 percent for conventional drop hammer using rope and cathead
 ER = 80 percent for automatic trip hammer

Corrections for rod length, hole size, and use of a liner may also be made if appropriate. In general, these are only significant in unusual cases or where there is significant variation from standard procedures. These corrections may be significant for evaluation of liquefaction. Information on these additional corrections may be found in Youd and Idriss (1997).

The N_{160} - ϕ_f correlation used is modified after Bowles (1977). The correlation of Peck et al., Hanson, and Thornburn (1974) falls within the ranges specified. Experience should be used to select specific values within the ranges. In general, finer materials or materials with significant silt-sized material will fall in the lower portion of the range. Coarser materials with less than five percent fines will fall in the upper portion of the ranges. The geologic history and angularity of the particles may also need to be considered when selecting a value for ϕ_f .

Care should be exercised when using other correlations of SPT results to soil parameters. Some published correlations are based on corrected values (N_{160}) and some are based on uncorrected values (N).

The designer should ascertain the basis of the correlation and use either N_{160} or N as appropriate.

Care should also be exercised when using SPT blow counts to estimate soil shear strength if in soils with coarse gravel, cobbles, or boulders. Large gravels, cobbles, or boulders could cause the SPT blow counts to be unrealistically high.

The secant friction angle, ϕ'_s , derived from the procedure to estimate the drained friction angle of gravels and rock fill materials depicted in Figure 10.4.6.2.4-1 is based on a straight line from the origin of a Mohr diagram to the intersection with the strength envelope at the effective normal stress. Thus, the angle derived is applicable only to analysis of field conditions subject to similar normal stresses. See Terzaghi et al. (1996) for additional details regarding this procedure.

Figure 10.4.6.2.4-1—Estimation of Drained Friction Angle of Gravels and Rock Fills (modified after Terzaghi et al., 1996)

10.4.6.3—Soil Deformation

Consolidation parameters C_c , C_r , and C_α should be determined from the results of one-dimensional consolidation tests. To assess the potential variability in the settlement estimate, the average, upper and lower bound values obtained from testing should be considered.

Preconsolidation stress may be determined from one-dimensional consolidation tests and in-situ tests. Knowledge of the stress history of the soil should be used to supplement data from laboratory and/or in-situ tests, if available.

C10.4.6.3

It is important to understand whether the values obtained are computed based on a void ratio definition or a strain definition. Computational methods vary for each definition.

For preliminary analyses or where accurate prediction of settlement is not critical, values obtained from correlations to index properties may be used. Refer to Sabatini et al. (2002) for discussion of the various correlations available. If correlations for prediction of settlement are used, their applicability to the specific geologic formation under consideration should be evaluated.

A profile of σ'_p , or $\text{OCR} = \sigma'_p / \sigma'_o$, with depth should be developed for the site for design applications where the stress history could have a significant impact on the design properties selected and the performance of the foundation. As with consolidation properties, an upper and lower bound profile should be developed based on laboratory tests and plotted with a profile based on particular in-situ test(s), if used. It is particularly important to accurately compute preconsolidation stress values for relatively shallow depths where in-situ effective stresses are low. An underestimation of the preconsolidation stress at shallow depths will result in overly conservative estimates of settlement for shallow soil layers.

The coefficient of consolidation, c_v , should be determined from the results of one-dimensional consolidation tests. The variability in laboratory determination of c_v results should be considered in the final selection of the value of c_v to be used for design.

Where evaluation of elastic settlement is critical to the design of the foundation or selection of the foundation type, in-situ methods such as pressuremeter testing (PMT) or DMT for evaluating the modulus of the stratum should be used.

Due to the numerous simplifying assumptions associated with conventional consolidation theory, on which the coefficient of consolidation is based, it is unlikely that even the best estimates of c_v from high-quality laboratory tests will result in predictions of time rate of settlement in the field that are significantly better than a prediction within one order of magnitude. In general, the in-situ value of c_v is larger than the value measured in the laboratory test. Therefore, a rational approach is to select average, upper, and lower bound values for the appropriate stress range of concern for the design application. These values should be compared to values obtained from previous work performed in the same soil deposit. Under the best-case conditions, these values should be compared to values computed from measurements of excess pore pressures or settlement rates during construction of other structures.

CPT in which the pore pressure dissipation rate is measured may be used to estimate the field coefficient of consolidation.

For preliminary analyses or where accurate prediction of settlement is not critical, values obtained from correlations to index properties presented in Sabatini et al. (2002) may be used.

For preliminary design or for final design where the prediction of deformation is not critical to structure performance, i.e., the structure design can tolerate the potential inaccuracies inherent in the correlations. The elastic properties (E_s , ν) of a soil may be estimated from empirical relationships presented in Table C10.4.6.3-1.

The specific definition of E_s is not always consistent for the various correlations and methods of in-situ measurement. See Sabatini et al. (2002) for additional details regarding the definition and determination of E_s .

An alternative method of evaluating the equivalent elastic modulus using measured shear wave velocities is presented in Sabatini et al. (2002).

Table C10.4.6.3-1—Elastic Constants of Various Soils (modified after U.S. Department of the Navy, 1982; Bowles, 1988)

	Typical Range of Young's Modulus Values, E_s (ksi)	Poisson's Ratio, ν (dim)
Soil Type		
Clay: Soft sensitive Medium stiff to stiff Very stiff	 0.347–2.08 2.08–6.94 6.94–13.89	 0.4–0.5 (undrained)
Loess Silt	 2.08–8.33 0.278–2.78	 0.1–0.3 0.3–0.35
Fine Sand: Loose Medium dense Dense	 1.11–1.67 1.67–2.78 2.78–4.17	 0.25
Sand: Loose Medium dense Dense	 1.39–4.17 4.17–6.94 6.94–11.11	 0.20–0.36 0.30–0.40
Gravel: Loose Medium dense Dense	 4.17–11.11 11.11–13.89 13.89–27.78	 0.20–0.35 0.30–0.40
Estimating E_s from SPT N Value		
Soil Type		E_s (ksi)
Silts, sandy silts, slightly cohesive mixtures		$0.056 N_{160}$
Clean fine to medium sands and slightly silty sands		$0.097 N_{160}$
Coarse sands and sands with little gravel		$0.139 N_{160}$
Sandy gravel and gravels		$0.167 N_{160}$
Estimating E_s from q_c (static cone resistance)		
Sandy soils		$0.028 q_c$

The modulus of elasticity for normally consolidated granular soils tends to increase with depth. An alternative method of defining the soil modulus for granular soils is to assume that it increases linearly with depth starting at zero at the ground surface in accordance with the following equation:

$$E_s = n_h \times z \quad (\text{C10.4.6.3-1})$$

where:

- E_s = the soil modulus at depth z (ksi)
 n_h = rate of increase of soil modulus with depth as defined in Table C10.4.6.3-2 (ksi/ft)
 z = depth below the ground surface (ft)

Table C10.4.6.3-2—Rate of Increase of Soil Modulus with Depth n_h (ksi/ft) for Sand

Consistency	Dry or Moist	Submerged
Loose	0.417	0.208
Medium	1.11	0.556
Dense	2.78	1.39

The potential for soil swell that may result in uplift on deep foundations or heave of shallow foundations should be evaluated based on Table 10.4.6.3-1.

Table 10.4.6.3-1—Method for Identifying Potentially Expansive Soils (Reese and O'Neill, 1988)

Liquid Limit LL (%)	Plastic Limit PL (%)	Soil Suction (ksf)	Potential Swell (%)	Potential Swell Classification
>60	>35	>8	>1.5	High
50–60	25–35	3–8	0.5–1.5	Marginal
<50	<25	<3	<0.5	Low

10.4.6.4—Rock Mass Strength

The strength of intact rock material should be determined using the results of unconfined compression tests on intact rock cores. If point load strength index tests are used to assess intact rock compressive strength in lieu of a full suite of unconfined compression tests on intact rock cores, the point load test results should be calibrated to unconfined compression strength tests obtained from the same geologic unit.

Except as noted for design of spread footings in rock, for a rock mass of “randomly” oriented discontinuities such that it contains a sufficient number behaves as an isotropic mass, and thus, its behavior is largely independent of the direction of the applied loads, the strength of the rock mass should first be classified using its geological strength index (GSI) as described in Figures 10.4.6.4-1 and 10.4.6.4-2, and then assessed using the Hoek–Brown failure criterion.

C10.4.6.4

Point load strength index tests rely on empirical correlations to intact rock compressive strength. The correlation provided in the ASTM point load test procedure (ASTM D5731) is empirically based and may not be valid for the specific rock type under consideration. Therefore, a site-specific correlation with uniaxial compressive strength test results from the same geologic unit is recommended. Point load strength index tests should not be used for weak to very weak rocks (< 2,200 psi/15 Mpa).

Because the engineering behavior of rock is strongly influenced by the presence and characteristics of discontinuities, emphasis is placed on visual assessment of the rock and the rock mass. The application of a rock mass classification system essentially assumes that the rock mass contains a sufficient number of “randomly” oriented discontinuities such that it behaves as an isotropic mass, and thus its behavior is largely independent of the direction of the applied loads. It is generally not appropriate to use such classification systems for rock masses with well defined, dominant structural fabrics or where the orientation of discrete, persistent discontinuities controls behavior to loading.

The GSI was introduced by Hoek et al. (1995) and Hoek and Brown (1997), and updated by Hoek et al.

(1998) to classify jointed rock masses. Marinos et al. (2005) provides a comprehensive summary of the applications and limitations of the GSI for jointed rock masses (see Figure 10.4.6.4-1) and for heterogeneous rock masses that have been tectonically disturbed (see Figure 10.4.6.4-2). Hoek et al. (2005) further distinguish heterogeneous sedimentary rocks that are not tectonically disturbed and provide several diagrams for determining GSI values for various rock mass conditions. In combination with rock type and uniaxial compressive strength of intact rock, q_u , GSI provides a practical means to assess rock mass strength and rock mass modulus for foundation design using the Hoek–Brown failure criterion (Hoek et al., 2002).

The design procedures for spread footings in rock provided in Article 10.6.3.2 have been developed using the geomechanical rock mass rating (RMR) system. For design of foundations in rock in Articles 10.6.2.4 and 10.6.3.2, classification of the rock mass should be according to the RMR system. For additional information on the RMR system, see Sabatini et al. (2002).

Other methods for assessing rock mass strength, including in-situ tests or other visual systems that have proven to yield accurate results may be used in lieu of the specified method.

GEOLOGICAL STRENGTH INDEX FOR JOINTED ROCKS (Hoek and Marinos, 2000) From the lithology, structure and surface conditions of the discontinuities, estimate the average value of GSI. Do not try to be too precise. Quoting a range from 33 to 37 is more realistic than stating that GSI = 35. Note that the table does not apply to structurally controlled failures. Where weak planar structural planes are present in an unfavourable orientation with respect to the excavation face, these will dominate the rock mass behaviour. The shear strength of surfaces in rocks that are prone to deterioration as a result of changes in moisture content will be reduced if water is present. When working with rocks in the fair to very poor categories, a shift to the right may be made for wet conditions. Water pressure is dealt with by effective stress analysis.		SURFACE CONDITIONS				
STRUCTURE		DECREASING SURFACE QUALITY →				
		VERY GOOD Very rough, fresh unweathered surfaces	GOOD Rough, slightly weathered, iron stained surfaces	FAIR Smooth, moderately weathered and altered surfaces	POOR Slackensided, highly weathered surfaces with compact coatings or fillings or angular fragments	VERY POOR Slackensided, highly weathered surfaces with soft clay coatings or fillings
	INTACT OR MASSIVE - intact rock specimens or massive in situ rock with few widely spaced discontinuities	90	80	70	N/A	N/A
	BLOCKY - well interlocked undisturbed rock mass consisting of cubical blocks formed by three intersecting discontinuity sets	80	70	60		
	VERY BLOCKY - interlocked, partially disturbed mass with multi-faceted angular blocks formed by 4 or more joint sets		60	50		
	BLOCKY/DISTURBED/SEAMY - folded with angular blocks formed by many intersecting discontinuity sets. Persistence of bedding planes or schistosity			40	30	
	DISINTEGRATED - poorly interlocked, heavily broken rock mass with mixture of angular and rounded rock pieces				20	
	LAMINATED/SHEARED - Lack of blockiness due to close spacing of weak schistosity or shear planes	N/A	N/A			10

Figure 10.4.6.4-1—Determination of GSI for Jointed Rock Mass (Hoek and Marinos, 2000)

Figure 10.4.6.4-2—Determination of GSI for Tectonically Deformed Heterogeneous Rock Masses (Marinos and Hoek, 2000)

The strength of jointed rock masses should be evaluated using the Hoek–Brown failure criterion (Hoek et al., 2002). This nonlinear strength criterion is expressed in its general form as:

$$\sigma_1' = \sigma_3' + q_u \left(m_b \frac{\sigma_3'}{q_u} + s \right)^a \quad (10.4.6.4-1)$$

in which:

$$s = e^{\left(\frac{GSI - 100}{9 - 3D} \right)} \quad (10.4.6.4-2)$$

$$a = \frac{1}{2} + \frac{1}{6} \left(e^{\frac{-GSI}{15}} - e^{\frac{-20}{3}} \right) \quad (10.4.6.4-3)$$

where:

- e = 2.718 (natural or Napierian log base)
- D = disturbance factor (dim)
- σ_1' and σ_3' = principal effective stresses (ksf)
- q_u = average unconfined compressive strength of rock core (ksf)
- m_b , s , and a = empirically determined parameters

The value of the constant m_i should be estimated from Table 10.4.6.4-1, based on lithology. Relationships between GSI and the parameters m_b , s , and a , according to Hoek et al. (2002) are as follows:

$$m_b = m_i e^{\left(\frac{GSI-100}{28-14D}\right)} \quad (10.4.6.4-4)$$

Table 10.4.6.4-1—Values of the Constant m_i by Rock Group (after Marinos and Hoek 2000; with updated values from Rocscience, Inc., 2007)

Rock type	Class	Group	Texture			
			Coarse	Medium	Fine	Very fine
SEDIMENTARY	Clastic		Conglomerate (21 ± 3)	Sandstone 17 ± 4	Siltstone 7 ± 2	Claystone 4 ± 2
			Breccia (19 ± 5)		Greywacke (18 ± 3)	Shale (6 ± 2)
						Marl (7 ± 2)
	Non-Clastic	Carbonates	Crystalline Limestone (12 ± 3)	Sparitic Limestone (10 ± 5)	Micritic Limestone (8 ± 3)	Dolomite (9 ± 3)
		Evaporites		Gypsum 10 ± 2	Anhydrite 12 ± 2	
		Organic				Chalk 7 ± 2
METAMORPHIC	Non Foliated		Marble 9 ± 3	Hornfels (19 ± 4)	Quartzite 20 ± 3	
				Metasandstone (19 ± 3)		
	Slightly foliated		Migmatite (29 ± 3)	Amphibolite 26 ± 6	Gneiss 28 ± 5	
	Foliated*			Schist (10 ± 3)	Phyllite (7 ± 3)	Slate 7 ± 4
IGNEOUS	Plutonic	Light	Granite 32 ± 3	Diorite 25 ± 5		
			Granodiorite (29 ± 3)			
		Dark	Gabbro 27 ± 3	Dolerite (16 ± 5)		
			Norite 20 ± 5			
	Hypabyssal		Porphyries (20 ± 5)		Diabase (15 ± 5)	Peridotite (25 ± 5)
	Volcanic	Lava		Rhyolite (25 ± 5)	Dacite (25 ± 3)	
				Andesite 25 ± 5	Basalt (25 ± 5)	
		Pyroclastic	Agglomerate (19 ± 3)	Volcanic breccia (19 ± 5)	Tuff (13 ± 5)	

* These values are for intact rock specimens tested normal to bedding or foliation. The value of m_i will be significantly different if failure occurs along a weakness plane.

Disturbance to the foundation excavation caused by the rock removal methodology should be considered through the disturbance factor, D , in Eqs. 10.4.6.4-2 through 10.4.6.4-4.

The disturbance factor, D , ranges from 0.0 (undisturbed) to 1.0 (highly disturbed), and is an adjustment for the rock mass disturbance induced by the excavation method. Suggested values for various tunnel and slope excavations can be found in Hoek et al. (2002).

Where it is necessary to evaluate the strength of a single discontinuity or set of discontinuities, the strength along the discontinuity should be determined as follows:

- For smooth discontinuities, the shear strength is represented by a friction angle of the parent rock material. To evaluate the friction angle of this type of discontinuity surface for design, direct shear tests on samples should be performed. Samples should be formed in the laboratory by cutting samples of intact core or, if possible, on actual discontinuities using an oriented shear box.
- For rough discontinuities, the nonlinear criterion of Barton (1976) should be applied or, if possible, direct shear tests should be performed on actual discontinuities using an oriented shear box.

However, these values may not directly applicable to foundations. If using blasting techniques to remove the rock in a shaft foundation, due to its confined state, a disturbance factor approaching 1.0 should be considered, as the blast energy will tend to radiate laterally into the intact rock, potentially disturbing the rock. If using rock coring techniques, much less disturbance is likely and a disturbance factor approaching zero may be considered. If using a down the hole hammer to break up the rock, the disturbance factor is likely between these two extremes.

The range of typical friction angles provided in Table C10.4.6.4-1 may be used in evaluating measured values of friction angles for smooth joints.

Table C10.4.6.4-1—Typical Ranges of Friction Angles for Smooth Joints in a Variety of Rock Types (modified after Barton, 1976 and Jaeger and Cook, 1976)

Rock Class	Friction Angle Range	Typical Rock Types
Low Friction	20–27°	Schists (high mica content), shale, marl
Medium Friction	27–34°	Sandstone, siltstone, chalk, gneiss, slate
High Friction	34–40°	Basalt, granite, limestone, conglomerate

Note: Values assume no infilling and little relative movement between joint faces.

When a major discontinuity with a significant thickness of infilling is to be investigated, the shear strength will be governed by the strength of the infilling material and the past and expected future displacement of the discontinuity. Refer to Sabatini et al. (2002) for detailed procedures to evaluate infilled discontinuities.

10.4.6.5—Rock Mass Deformation

The elastic modulus of a rock mass, E_m , shall be taken as the lesser of the intact modulus of a sample of rock core, E_R , or the modulus determined from Table 10.4.6.5-1.

For critical or large structures, determination of rock mass modulus, E_m , using in-situ tests should be considered. Refer to Sabatini et al. (2002) for descriptions of suitable in-situ tests.

C10.4.6.5

Methods for establishing design values of E_m include:

- Empirical correlations that relate E_m to strength or modulus values of intact rock (q_u or E_R) and GSI;
- Estimates based on previous experience in similar rocks or back-calculated from load tests; and
- In-situ testing, such as pressuremeter test.

Empirical correlations that predict rock mass modulus, E_m , from GSI and properties of intact rock, either uniaxial compressive strength, q_u , or intact modulus, E_R , are presented in Table 10.4.6.5-1. The recommended approach is to measure uniaxial

compressive strength and modulus of intact rock in laboratory tests on specimens prepared from rock core. Values of GSI should be determined for representative zones of rock for the particular foundation design being considered. The correlation equations in Table 10.4.6.5-1 should then be used to evaluate modulus and its variation with depth. If pressuremeter tests are conducted, it is recommended that measured modulus values be calibrated to the values calculated using the relationships in Table 10.4.6.5-1.

Preliminary estimates of the elastic modulus of intact rock may be made from Table C10.4.6.5-1. Note that some of the rock types identified in the Table are not present in the United States.

It is extremely important to use the elastic modulus of the rock mass for computation of displacements of rock materials under applied loads. Use of the intact modulus will result in unrealistic and unconservative estimates.

Table 10.4.6.5-1—Estimation of E_m Based on GSI

Expression	Notes/Remarks	Reference
$E_m (GPa) = \sqrt{\frac{q_u}{100}} 10^{\frac{GSI-10}{40}} \quad \text{for } q_u \leq 100 \text{ MPa}$	Accounts for rocks with $q_u < 100$ Mpa; notes q_u in Mpa	Hoek and Brown (1997); Hoek et al. (2002)
$E_m (GPa) = 10^{\frac{GSI-10}{40}} \quad \text{for } q_u > 100 \text{ MPa}$		
$E_m = \frac{E_R}{100} e^{\frac{GSI}{21.7}}$	Reduction factor on intact modulus, based on GSI	Yang (2006)
Notes: E_r = modulus of intact rock, E_m = equivalent rock mass modulus, GSI = geological strength index, q_u = uniaxial compressive strength, and 1 Mpa = 20.9 ksf.		

Table C10.4.6.5-1—Summary of Elastic Moduli for Intact Rock (modified after Kulhawy, 1978)

Rock Type	No. of Values	No. of Rock Types	Elastic Modulus, E_R (ksi $\times 10^3$)			Standard Deviation (ksi $\times 10^3$)
			Maximum	Minimum	Mean	
Granite	26	26	14.5	0.93	7.64	3.55
Diorite	3	3	16.2	2.48	7.45	6.19
Gabbro	3	3	12.2	9.8	11.0	0.97
Diabase	7	7	15.1	10.0	12.8	1.78
Basalt	12	12	12.2	4.20	8.14	2.60
Quartzite	7	7	12.8	5.29	9.59	2.32
Marble	14	13	10.7	0.58	6.18	2.49
Gneiss	13	13	11.9	4.13	8.86	2.31
Slate	11	2	3.79	0.35	1.39	0.96
Schist	13	12	10.0	0.86	4.97	3.18
Phyllite	3	3	2.51	1.25	1.71	0.57
Sandstone	27	19	5.68	0.09	2.13	1.19
Siltstone	5	5	4.76	0.38	2.39	1.65
Shale	30	14	5.60	0.001	1.42	1.45
Limestone	30	30	13.0	0.65	5.7	3.73
Dolostone	17	16	11.4	0.83	4.22	3.44

Poisson's ratio for rock should be determined from tests on intact rock core.

Where tests on rock core are not practical, Poisson's ratio may be estimated from Table C10.4.6.5-2.

Table C10.4.6.5-2—Summary of Poisson's Ratio for Intact Rock (modified after Kulhawy, 1978)

Rock Type	No. of Values	No. of Rock Types	Poisson's Ratio, ν			Standard Deviation
			Maximum	Minimum	Mean	
Granite	22	22	0.39	0.09	0.20	0.08
Gabbro	3	3	0.20	0.16	0.18	0.02
Diabase	6	6	0.38	0.20	0.29	0.06
Basalt	11	11	0.32	0.16	0.23	0.05
Quartzite	6	6	0.22	0.08	0.14	0.05
Marble	5	5	0.40	0.17	0.28	0.08
Gneiss	11	11	0.40	0.09	0.22	0.09
Schist	12	11	0.31	0.02	0.12	0.08
Sandstone	12	9	0.46	0.08	0.20	0.11
Siltstone	3	3	0.23	0.09	0.18	0.06
Shale	3	3	0.18	0.03	0.09	0.06
Limestone	19	19	0.33	0.12	0.23	0.06
Dolostone	5	5	0.35	0.14	0.29	0.08

10.4.6.6—Erodibility of Rock

Consideration should be given to the physical characteristics of the rock and the condition of the rock mass when determining a rock's susceptibility to erosion in the vicinity of bridge foundations. Physical characteristics that should be considered in the assessment of erodibility include cementing agents, mineralogy, unconfined compressive strength, rock quality designation (RQD), joint spacing and orientation, joint roughness and alteration, and weathering.

C10.4.6.6

There is no consensus on how to determine erodibility of rock masses near bridge foundations. Refer to HEC-18 (FHWA, 2012) and Arneson et al. (2012) when determining the potential for a rock mass to scour.

10.5—LIMIT STATES AND RESISTANCE FACTORS

10.5.1—General

The limit states shall be as specified in Article 1.3.2; foundation-specific provisions are contained in this Section.

Foundations shall be proportioned so that the factored resistance is not less than the effects of the factored loads specified in Section 3.

Changes in foundation conditions resulting from scour, as specified in Article 2.6.4.4.4, shall be considered.

10.5.2—Service Limit States

10.5.2.1—General

Foundation design at the service limit state shall include:

- vertical movements (settlements),

C10.5.2.1

In bridges where the superstructure and substructure are not integrated, settlement corrections can be made by jacking and shimming bearings. Article 2.5.2.3 requires jacking provisions for these bridges.

- horizontal movements, and
- scour design flood.

Consideration of foundation movements shall be based upon structure tolerance to total and differential movements, rideability and economy. Foundation movements shall include all movement from settlement, horizontal movement, and rotation.

Bearing resistance estimated using the presumptive allowable bearing pressure for spread footings, if used, shall be applied only to address the service limit state.

The foundation movements shall be translated to the deck elevation to evaluate the effect of such movements on the superstructure.

10.5.2.2—Tolerable Movements and Movement Criteria

10.5.2.2.1—General

Foundation movement criteria shall be consistent with the function and type of structure, anticipated service life, and consequences of unacceptable movements on structure performance. Foundation movement shall include vertical, horizontal, and rotational movements. The tolerable movement criteria shall be established by either empirical procedures or structural analyses, or by consideration of both.

Foundation settlement shall be investigated using all applicable loads in the Service I Load Combination specified in Table 3.4.1-1. Transient loads may be omitted from settlement analyses for foundations bearing on or in cohesive soil deposits that are subject to time-dependent consolidation settlements.

All applicable service limit state load combinations in Table 3.4.1-1 shall be used for evaluating horizontal movement and rotation of foundations.

The cost of limiting foundation movements should be compared with the cost of designing the superstructure so that it can tolerate larger movements or of correcting the consequences of movements through maintenance to determine minimum lifetime cost. The Owner may establish more stringent criteria.

The scour design flood is defined in Article 2.6.4.4 and its consideration under the service limit state specified in Article 2.6.4.4.4.

Presumptive bearing pressures were developed for use with working stress design. These values may be used for preliminary sizing of foundations, but should generally not be used for final design. If used for final design, presumptive values are only applicable at service limit states.

Movements of the substructure, i.e., elements between foundation and superstructure, should be added to foundation movements as appropriate.

C10.5.2.2.1

Experience has shown that bridges can and often do accommodate more movement and/or rotation than traditionally allowed or anticipated in design. Creep, relaxation, redistribution of force effects, as well as the conservatism inherent in the estimation of force effects by simplified methods accommodate these movements. Rotation movements should be evaluated at the top of the substructure unit in plan location and at the deck elevation.

Previous studies recommended differential settlement limits based on a factor applied to span length (Moulton et al., 1985) (DiMillio, 1982) (Barker et al., 1991). Romano et al. (2017) developed separate differential settlement limits based on the differences in force effects computed from the live load distribution factor method (Article 4.6.2.2) and refined analysis. These limits apply to simple span and continuous multi-girder bridges constructed of steel and prestressed concrete that (a) meet the criteria for straight girders given in Article 4.6.1.2.4b, (b) have skew angles less than 45 degrees, and (c) were designed using the live load distribution factor method (Article 4.6.2.2).

To address bridge rideability, the angular break caused by differential settlement between either adjacent spans, or a span and the approach slab, should be limited to 0.004 radians. This criteria will always govern simply supported bridges and may govern continuous bridges.

For continuous steel girder bridges, the differential settlement limit was governed by the Strength I limit state and was found to be influenced by the girder spacing as well as the span length. The following expression may be used to estimate the tolerable differential settlement for continuous steel multi-girder bridges.

$$\Delta = 0.55 \frac{L}{S} - 2.6 \quad (\text{C10.5.2.2.1-1})$$

Where S is the girder spacing, in ft; L is the minimum of adjacent span lengths, in ft; and Δ is the tolerable differential settlement, in inches.

For prestressed concrete girders rendered continuous for live load, the tension stress check of the Service III limit state controlled the level of tolerable differential settlement and resulted in relatively small tolerance. The following expression may be used to estimate the tolerable differential settlement for prestressed concrete multi-girder bridges rendered continuous for live load.

$$\Delta = 0.006L + 0.17 \quad (\text{C10.5.2.2.1-2})$$

If Service III limits are ignored, the controlling case for prestressed concrete multi-girder bridge rendered continuous for live load becomes Strength I, and the tolerable differential settlement may be estimated by the following expression.

$$\Delta = 0.13 \frac{L}{S} - 0.17 \quad (\text{C10.5.2.2.1-3})$$

As indicated in Table 3.4.1-1, the effects of settlement may need to be included in the evaluation of several different load combinations, including strength and service limit states. The estimation of differential settlement demands used in these evaluations should be computed using the Service I load combination.

For preliminary design, the previously developed limits of angular distortion between adjacent foundations of 0.004 rad. in continuous spans may be used for steel bridges.

Other angular distortion limits may be appropriate after consideration of:

- cost of mitigation through larger foundations, realignment or surcharge,
- rideability,
- vertical clearance,
- tolerable limits of deformation of other structures associated with a bridge, e.g., approach slabs, wing walls, pavement structures, drainage grades, utilities on the bridge,
- roadway drainage,
- aesthetics, and
- safety.

Horizontal movement criteria should be established at the top of the foundation based on the tolerance of the structure to lateral movement, with consideration of the column length and stiffness.

Tolerance of the superstructure to lateral movement will depend on bridge seat or joint widths, bearing type(s), structure type, and load distribution effects.

10.5.3.2—Spread Footings

The design of spread footings at the strength limit state shall also consider:

- nominal bearing resistance,
- overturning or excessive loss of contact,
- sliding at the base of footing, and
- constructability.

10.5.3.3—Driven Piles

The design of pile foundations at the strength limit state shall also consider:

- axial compression resistance for single piles;
- pile group compression resistance;
- uplift resistance for single piles;
- uplift resistance for pile groups;
- pile punching failure into a weaker stratum below the bearing stratum;
- single pile and pile group lateral resistance; and
- constructability, including pile drivability.

10.5.3.4—Drilled Shafts

The design of drilled shaft foundations at the strength limit state shall also consider:

- axial compression resistance for single drilled shafts;
- shaft group compression resistance;
- uplift resistance for single shafts;
- uplift resistance for shaft groups;
- single shaft and shaft group lateral resistance;
- shaft punching failure into a weaker stratum below the bearing stratum; and
- constructability, including method(s) of shaft construction.

10.5.3.5—Micropiles

The design of micropile foundations at the strength limit state shall also consider:

- axial compression resistance for single micropile;
- micropile group compression resistance;
- uplift resistance for single micropile;
- uplift resistance for micropile groups;

C10.5.3.2

The Designer should consider whether special construction methods are required to bear a spread footing at the design depth. Consideration should be given to the potential need for shoring, cofferdams, seals, and/or dewatering. Basal stability of excavations should be evaluated, particularly if dewatering or cofferdams are required.

Efforts should be made to identify the presence of expansive/collapsible soils in the vicinity of the footing. If present, the structural design of the footing should be modified to accommodate the potential impact to the performance of the structure, or the expansive/collapsible soils should be removed or otherwise remediated. Special conditions such as the presence of karstic formations or mines should also be evaluated, if present.

C10.5.3.3

The commentary in Article C10.5.3.2 is applicable if a pile cap is needed.

For pile foundations, as part of the evaluation for the geotechnical strength limit states identified herein, soil setup or relaxation, and buoyancy due to groundwater should be evaluated. As part of the evaluation for the structural strength limit state, the effects of drag load should be evaluated.

C10.5.3.4

See Articles C10.5.3.2 and C10.5.3.3.

The design of drilled shafts for each of these limit states should include the effects of the method of construction, including construction sequencing, whether the shaft will be excavated in the dry or if wet methods must be used, as well as the need for temporary or permanent casing to control caving ground conditions. The design assumptions regarding construction methods must carry through to the contract documents to provide assurance that the geotechnical and structural resistance used for design will be provided by the constructed product.

C10.5.3.5

Article C10.5.3.2 is applicable if a pile cap is needed.

The design of micropiles for each of these limit states should include the effects of the method of construction for the micropile type to be constructed. The design assumptions regarding construction methods must carry through to the contract documents to provide assurance that the geotechnical and structural resistance used for design will be provided by the constructed product.

- loss in strength in the liquefied layer or layers,
- liquefaction-induced ground settlement, and
- flow failures, lateral spreading, and slope instability.

For sites where liquefaction occurs around bridge foundations, bridges should be analyzed and designed in two configurations as follows:

- *Nonliquefied Configuration*—The structure should be analyzed and designed, assuming no liquefaction occurs, using the ground response spectrum appropriate for the site soil conditions in a nonliquefied state.
- *Liquefied Configuration*—The structure as designed in nonliquefied configuration above should be reanalyzed assuming that the layer has liquefied and the liquefied soil provides the appropriate residual resistance for lateral and axial deep foundation response analyses consistent with liquefied soil conditions (i.e., modified p - y curves, modulus of subgrade reaction, or t - z curves). The design spectrum should be the same as that used in the nonliquefied configuration.

With the Owner's approval, or as required by the Owner, a site-specific response spectrum that accounts for the modifications in spectral content from the liquefying soil may be developed. Unless approved otherwise by the Owner, the reduced response spectrum resulting from the site-specific analyses shall not be less than two-thirds of the spectrum developed at the ground surface using the general procedure described in Article 3.10.4.1.

The Designer should provide explicit detailing of plastic hinging zones for both cases mentioned above since it is likely that locations of plastic hinges for the liquefied configuration are different than locations of plastic hinges for the nonliquefied configuration. Design requirements including shear reinforcement should be met for the liquefied and nonliquefied configuration. Where liquefaction is identified, plastic hinging in the foundation may be permitted with the Owner's approval.

For those sites where liquefaction-related permanent lateral ground displacements (e.g., flow, lateral spreading, or slope instability) are determined to occur, the effects of lateral displacements on the bridge and retaining structures should be evaluated. These effects can include increased lateral pressure on bridge foundations and retaining walls.

Methods used to assess the potential for liquefaction range from empirically-based design methods to complex numerical, effective stress methods that can model the time-dependent generation of pore-water pressure and its effect on soil strength and deformation. Furthermore, dynamic soil tests such as cyclic simple shear or cyclic triaxial tests can be used to assess liquefaction susceptibility and behavior to be used as input for liquefaction analysis and design.

The most common method of assessing liquefaction involves the use of empirical methods (e.g., Idriss and Boulanger, 2008). These methods provide an estimate of liquefaction potential based on SPT blow counts, CPT cone tip resistance, or shear wave velocity. This type of analysis should be conducted as a baseline evaluation, even when more rigorous methods are used.

A report from National Academies Press (2021) summarizes the consensus of the profession up to about the year 2014. The report provides background on several simplified methods (e.g., Boulanger and Idriss [2014] for SPT and Boulanger and Idriss [2015] for CPT) that can be considered for use.

The simplified empirical methods are suited for use to a maximum depth of approximately 75.0 ft. This depth limit relates to the database upon which the original empirical method was developed. Most of the database was from observations of liquefaction at depths less than 50.0 to 60.0 ft. Extrapolation of the simplified method beyond 75.0 ft is therefore of uncertain validity. This limitation should not be interpreted as meaning liquefaction does not occur beyond 75.0 ft. Rather, different methods should be used for greater depths, including the use of site-specific ground motion response modeling in combination with liquefaction testing in the laboratory.

The magnitude for the design earthquake must be determined when conducting liquefaction assessments using the simplified empirical procedures. The earthquake magnitude used to assess liquefaction can be determined from earthquake disaggregation data for the site, available through the United States Geological Survey national seismic hazard model (NSHM) web tool. If a single or a few larger-magnitude earthquakes dominate the disaggregation, the magnitude of the single dominant earthquake or the mean of the few dominant earthquakes in the disaggregation should be used.

Liquefaction is generally limited to granular soils, such as sands and nonplastic silts. Loose gravels also can liquefy if drainage is prevented such as might occur if a layer of clay or frozen soil is located over the gravel. Methods for eliminating sites with low liquefaction triggering potential based on soil type have been developed, as discussed by Youd et al. (2001), Bray and Sancio (2006), and Boulanger and Idriss (2006). These

The effects of liquefaction-related, permanent lateral ground displacements on bridge and retaining wall performance should be considered separate from the inertial evaluation of the bridge structures. However, if large magnitude earthquakes dominate the seismic hazards, the bridge response evaluation should consider the potential simultaneous occurrence of:

- inertial response of the bridge, and loss in ground response from liquefaction around the bridge foundations, and
- predicted amounts of permanent lateral displacement of the soil.

If inelastic deformations are expected in the foundation due to liquefaction-induced effects, a quantitative assessment of such effects should be considered. Such assessment may follow the approach outlined for Seismic Design Category D in the *AASHTO Guide Specifications for LRFD Seismic Bridge Design*.

methods can be used to screen the potential for liquefaction triggering in certain soil types. In the past screening in soils with high silt or clay content was done using the Chinese criteria (Kramer, 1996). Studies by Bray and Sancio (2006) and by Boulanger and Idriss (2006) indicate that the Chinese criteria are unconservative, and therefore they should not be used.

Three criteria for assessing liquefaction susceptibility of soils have been developed as replacements to the Chinese criteria:

- Boulanger and Idriss (2006) recommend considering a soil to have clay-like behavior (i.e., not susceptible to liquefaction) if the plasticity index, $PI, \geq 7$.
- Bray and Sancio (2006) suggest that a soil with a $PI < 12$ and a ratio of water content to liquid limit, $w/LL > 0.85$ will be susceptible to liquefaction.
- For CPT data, Robertson and Wride (1998) suggest that the soils with a Soil Behavior Type index value, I_c , of less than 2.60 tend to exhibit sand-like behaviors; Robertson and Cabal (2015) later define a transition zone between sand- and clay-like behavior of $2.50 < I_c < 2.70$. For soils with I_c values in this transition region, samples should be obtained to verify behavior.

There is no current consensus on the preferred of these criteria, and, therefore, any of these methods may be used, unless the Owner has a specific preference.

To determine the location of soils that are adequately saturated for liquefaction to occur, the seasonally averaged groundwater elevation should be used. Groundwater fluctuations caused by tidal action or seasonal variations will cause the soil to be saturated only during a limited period of time, significantly reducing the risk that liquefaction could occur within the zone of fluctuation.

Liquefaction evaluation is required only for sites meeting requirements for Seismic Zones 3 and 4, provided that the soil is saturated and of a type that is susceptible to liquefaction. For loose to very loose sand sites (e.g., $N_{160} < 10$ bpf or $q_{c1N} < 75$), a potential exists for liquefaction in Seismic Zone 2, if A_s is 0.15 or higher. The potential for and consequences of liquefaction for these sites will depend on the dominant magnitude for the seismic hazard. As the magnitude decreases, the liquefaction potential of the soil increases due to the limited number of earthquake loading cycles. Generally, if the magnitude is 6 or less, even in these very loose soils, either the potential for liquefaction is very low or the extent of liquefaction is very limited. Nevertheless, a liquefaction assessment should be made if loose to very loose sands are present to a sufficient extent to impact bridge stability and A_s is greater than or equal to 0.15. These loose-to-very-loose sands are likely to be present in hydraulically placed fills and alluvial or estuarine deposits near rivers and waterfronts.

During liquefaction, pore-water pressure build-up occurs, resulting in loss of strength and then settlement as the excess pore-water pressures dissipate after the earthquake. The potential effects of strength loss and settlement include:

- *Slope Failure, Flow Failure, or Lateral Spreading*—The strength loss associated with pore-water pressure build-up can lead to slope instability. Generally, if the factor of safety against liquefaction is less than approximately 1.2 to 1.3, a potential for pore-water pressure build-up will occur, and the effects of this build-up should be assessed. If the soil liquefies, the stability is determined by the residual strength of the soil. The residual strength of liquefied soils can be determined using empirical methods developed by Seed and Harder (1990), Olson and Stark (2002), Idriss and Boulanger (2007), Robertson (2010), Kramer and Wang (2015), and others (see National Academies, 2021). Loss of lateral resistance can allow abutment soils to move laterally, resulting in bridge substructure distortion and unacceptable deformations and moments in the superstructure.
- *Reduced Foundation Bearing Resistance*—Liquefied strength is often a fraction of nonliquefied strength. This loss in strength can result in large displacements or bearing failure. For this reason, spread footing foundations are not recommended where liquefiable soils occur unless the spread footing is located below the maximum depth of liquefaction or soil improvement techniques are used to mitigate the effects of liquefaction.
- *Reduced Soil Stiffness and Loss of Lateral Support for Deep Foundations*—This loss in strength can change the lateral response characteristics of piles and shafts under lateral load.
- *Vertical Ground Settlement as Excess Pore-water Pressures Induced by Liquefaction Dissipate, Resulting in Drag Loads on Deep Foundations*—If liquefaction-induced drag loads can occur, the drag loads should be assessed as specified in Article 3.11.8.

Most liquefaction-related damage to bridges during past earthquakes has been the result of lateral movement of the soil, causing severe column distortion and potential structure collapse. Therefore, a thorough analysis of the effects of lateral soil movement due to liquefaction on the structure is necessary. If there is potential for significant soil movement, the structure design should meet the requirements of Seismic Zone 4.

The effects of liquefaction will depend in large part on the amount of soil that liquefies and the location of the liquefied soil with respect to the foundation. On sloping ground, lateral flow, spreading, and slope instability can occur on relatively thin layers of liquefiable soils, whereas the effects of thin liquefied layer on the lateral response of piles or shafts (without lateral ground

will be smaller or could be increased over nonliquefied conditions in the longer period range over about 1–2 sec. The developer of the site response analysis should capture accurate estimates of response for all periods that could be of importance in both nonliquefied and liquefied conditions.

The timing of liquefaction relative to the development of strong shaking also can be an important consideration for sites where lateral ground movement occurs. Both the development of liquefaction and the ground movement are dependent on the size and magnitude of the earthquake, but they do not necessarily occur at the same time. This issue is especially important when determining how to combine the inertial response of the structure and kinematic loading from lateral movement of the soil against the foundations and other substructure elements due to lateral spreading, slope instability, and flow failure. Current practice is to consider these two mechanisms to be independent, and therefore, the analyses are decoupled; i.e., the analysis is first performed to evaluate inertial effects during liquefaction following the same guidance as for level-ground sites, and then the foundation is evaluated for the moving ground, but without the inertial effects of the bridge superimposed. For critical bridges or in areas where very large-magnitude earthquakes could occur, detailed studies addressing the two mechanisms acting concurrently may be warranted. This timing issue also affects liquefaction-induced downdrag, in that settlement and downdrag generally does not occur until the pore pressures induced by ground shaking begin to dissipate after shaking ceases.

For assessment of existing structures, the Designer should consider using Seismic Zone 4 regardless of the magnitude of A_s , even when significant lateral soil movement is not expected, if the structure is particularly weak with regard to its ability to resist the forces and displacements that could be caused by liquefaction. Examples of weaknesses that could exacerbate the impact of liquefaction to the structure include presence of shallow foundations, deep foundations tipped in liquefiable soil, very limited bridge support lengths that have little tolerance of lateral movement of the substructure, deterioration of superstructure or substructure components due to advanced age of the structure or severe environmental conditions, and the absence of substructure redundancy.

The intent of these Specifications is to limit inelastic deformations under seismic loading to above-ground locations that can be inspected. However, if liquefaction occurs, it may be difficult or impossible to restrict inelastic action solely to above-ground locations without site improvement. If inelastic deformations are expected in the foundation, then the Owner may consider installation of devices that permit post-earthquake assessment; for example, installation of inclinometer tubes in drilled shafts permits limited evaluation of the deformations of the foundation, which would otherwise be impossible to inspect at any significant depth.

Permitting inelastic behavior below the ground implies that the shaft or piles will be damaged, possibly along with other parts of the bridge, and may need to be replaced.

Design options range from (a) an acceptance of the movements with significant damage to the piles and columns if the movements are large (possibly requiring demolition but still preserving the no-collapse philosophy) to (b) designing the piles to resist the forces generated by lateral spreading. Between these options are a range of mitigation measures to limit the amount of movement to tolerable levels for the desired performance objective. However, tolerable structural movements should be evaluated quantitatively.

Quantitative assessments of liquefaction-induced deformations on foundations may be accomplished using the nonlinear static “push over” methodology. However, such analysis is complicated by the need to model nonlinear p - y behavior of the liquefied soil along with the nonlinear behavior of the structure. Analyses where the liquefied soil is represented by appropriate residual resistance (p - y curves or modulus of subgrade reaction values) will generally provide conservative results for the actual inelastic behavior of the foundation structural elements. The approach for such analyses should be developed on a case-by-case basis due to the varied conditions found in liquefiable sites. Careful coordination between the geotechnical and structural engineers is essential to estimating the expected response and to evaluating whether the structure can tolerate the response. Often mitigation strategies may be required to reduce structural movements.

Mitigation of the effects of liquefaction-induced settlement or lateral soil movement may include ground stabilization to either prevent liquefaction or add strength to keep soil deformation from occurring, foundation or superstructure modifications to resist the forces and accommodate the deformations that may occur, or both.

It is often cost prohibitive to design the bridge foundation system to resist the loads imposed by liquefaction-induced lateral loads, especially if the depth of liquefaction extends more than about 20.0 ft below the ground surface and if a nonliquefied crust is part of the failure surface. Ground improvement to mitigate the liquefaction hazard is the likely alternative if it is not practical to design the foundation system to accommodate the lateral loads.

The primary ground improvement techniques to mitigate liquefaction fall into five general categories, namely removal and replacement, densification, reinforcement, altering the soil composition, and enhanced drainage. Any one or a combination of methods can be used. However, drainage improvement is not currently considered adequately reliable to prevent liquefaction-induced, excess pore-water pressure build-up due to (1) the time required for excess pore-water pressures to dissipate through the drainage paths, and (2) the potential for drainage materials to become clogged during installation and in service. In addition, with drainage enhancements

some settlement is still likely. Therefore, drainage enhancements should not be used as a means to fully mitigate liquefaction. For further discussion of ground improvement methods, see FHWA-SA-98-086, *Ground Improvement Technical Summaries* (Elias et al., 2000); FHWA-SA-95-037; Geotechnical Engineering Circular No. 1, *Dynamic Compaction* (Lukas, 1995); and FHWA/RD-83/O2C, *Design and Construction of Stone Columns* (Barkdale and Bachus, 1983).

The use of large diameter shafts in lieu of the conventional pile cap foundation type may be considered in order to achieve the lateral strength and stiffness required to sustain the column demand while minimizing the foundation exposed surface area normal to the lateral flow direction.

10.5.5—Resistance Factors

10.5.5.1—Service Limit States

Resistance factors for the service limit states shall be taken as 1.0.

A resistance factor of 1.0 shall be used to assess the ability of the foundation to meet the specified deflection criteria after soil removal due to the scour design flood.

10.5.5.2—Strength Limit States

10.5.5.2.1—General

Resistance factors for different types of foundation systems at the strength limit state shall be taken as specified in Articles 10.5.5.2.2, 10.5.5.2.3, 10.5.5.2.4, and 10.5.5.2.5, unless regionally specific values or substantial successful experience is available to justify higher values.

For overall stability, resistance factors shall be as specified in Article 11.6.3.7. Overall stability of foundations shall be investigated using Strength I load combination and the provisions of Article 3.4.1.

C10.5.5.2.1

Regionally specific values should be determined based on substantial statistical data combined with calibration or substantial successful experience to justify higher values. Smaller resistance factors should be used if site or material variability is anticipated to be unusually high or if design assumptions are required that increase design uncertainty that have not been mitigated through conservative selection of design parameters.

Certain resistance factors in Articles 10.5.5.2.2, 10.5.5.2.3, 10.5.5.2.4, and 10.5.5.2.5 are presented as a function of soil type, e.g., sand or clay. Naturally occurring soils do not fall neatly into these two classifications. In general, the terms “sand” and “cohesionless soil” may be connoted to mean drained conditions during loading, while “clay” or “cohesive soil” imply undrained conditions. For other or intermediate soil classifications, such as silts or gravels, the designer should choose, depending on the load case under consideration, whether the resistance provided by the soil will be a drained or undrained strength, and select the method of computing resistance and associated resistance factor accordingly.

In general, resistance factors for bridge and other structure design have been derived to achieve a reliability index, β , of 3.5, an approximate probability of failure, P_f , of 1 in 5,000. However, past geotechnical design practice has resulted in an effective reliability index, β , of 3.0, or an approximate probability of a failure of 1 in 1,000, for foundations in general, and for highly redundant systems,

such as pile groups, an approximate reliability index, β , of 2.3, an approximate probability of failure of 1 in 100 (Zhang et al., 2001) (Paikowsky et al., 2004) (Allen, 2005). If the resistance factors provided in this Article are adjusted to account for regional practices using statistical data and calibration, they should be developed using the β values provided above, with consideration given to the redundancy in the foundation system.

For bearing resistance, lateral resistance, and uplift calculations, the focus of the calculation is on the individual foundation element, e.g., a single pile or drilled shaft. Since these foundation elements are usually part of a foundation unit that contains multiple elements, failure of one of these foundation elements usually does not cause the entire foundation unit to reach failure, i.e., due to load sharing and overall redundancy. Therefore, the reliability of the foundation unit is usually more, and in many cases considerably more, than the reliability of the individual foundation element. Hence, a lower reliability can be successfully used for redundant foundations than is typically the case for the superstructure.

Note that not all of the resistance factors provided in this Article have been derived using statistical data from which a specific β value can be estimated, since such data were not always available. In those cases, where data were not available, resistance factors were estimated through calibration by fitting to past ASD safety factors, e.g., the AASHTO *Standard Specifications for Highway Bridges* (2002).

Additional discussion regarding the basis for the resistance factors for each foundation type and limit state is provided in Articles 10.5.5.2.2, 10.5.5.2.3, 10.5.5.2.4, and 10.5.5.2.5. Additional, more detailed information on the development of the resistance factors for foundations provided in this Article, and a comparison of those resistance factors to previous ASD practice, e.g., AASHTO (2002), is provided in Allen (2005).

Design for the scour design flood must satisfy the requirement that the factored foundation resistance is greater than the factored load determined with the scoured soil removed.

The foundation resistance after the scour design flood shall provide adequate foundation resistance using the resistance factors given in this Article. The resistance factors shall be those used in the Strength Limit State, without scour

10.5.5.2.2—Spread Footings

C10.5.5.2.2

The resistance factors provided in Table 10.5.5.2.2-1 shall be used for strength limit state design of spread footings, with the exception of the deviations allowed for local practices and site-specific considerations in Article 10.5.5.2.

Table 10.5.5.2.2-1—Resistance Factors for Geotechnical Resistance of Shallow Foundations at the Strength Limit State

Method/Soil/Condition			Resistance Factor
Bearing Resistance	ϕ_b	Theoretical method (Munfakh et al., 2001), in clay	0.50
		Theoretical method (Munfakh et al., 2001), in sand, using CPT	0.50
		Theoretical method (Munfakh et al., 2001), in sand, using SPT	0.45
		Semi-empirical methods (Meyerhof, 1957), all soils	0.45
		Footings on rock	0.45
		Plate Load Test	0.55
Sliding	ϕ_t	Precast concrete placed on sand	0.90
		Cast-in-place concrete on sand	0.80
		Cast-in-place or precast concrete on clay	0.85
		Soil on soil	0.90
	ϕ_{ep}	Passive earth pressure component of sliding resistance	0.50

The resistance factors in Table 10.5.5.2.2-1 were developed using both reliability theory and calibration by fitting to Allowable Stress Design (ASD). In general, ASD safety factors for footing bearing capacity range from 2.5 to 3.0, corresponding to a resistance factor of approximately 0.55 to 0.45, respectively, and for sliding, an ASD safety factor of 1.5, corresponding to a resistance factor of approximately 0.9. Calibration by fitting to ASD controlled the selection of the resistance factor in cases where statistical data were limited in quality or quantity.

The resistance factor for sliding of cast-in-place concrete on sand is slightly lower than the other sliding resistance factors based on reliability theory analysis (Barker et al., 1991). The higher interface friction coefficient used for sliding of cast-in-place concrete on sand relative to that used for precast concrete on sand causes the cast-in-place concrete sliding analysis to be less conservative, resulting in the need for the lower resistance factor. A more detailed explanation of the development of the resistance factors provided in Table 10.5.5.2.2-1 is provided in Allen (2005).

The resistance factors for plate load tests and passive resistance were based on engineering judgment and past ASD practice.

10.5.5.2.3—Driven Piles

Resistance factors shall be selected from Table 10.5.5.2.3-1 based on the method used for determining the driving criterion necessary to achieve the required nominal pile bearing resistance.

Regarding load tests, and dynamic tests with signal matching, the number of tests to be conducted to justify the design resistance factors selected should be based on the variability in the properties and geologic stratification of the site to which the test results are to be applied. A site shall be defined as a project site, or a portion of it, where the subsurface conditions can be characterized as geologically similar in terms of subsurface stratification, i.e., sequence, thickness, and geologic history of strata, the engineering properties of the strata, and groundwater conditions.

C10.5.5.2.3

Where nominal pile bearing resistance is determined by static load test, dynamic testing, wave equation, or dynamic formulas, the uncertainty in the nominal resistance is strictly due to the reliability of the resistance determination method used in the field during pile installation.

In most cases, the nominal bearing resistance of each production pile is field-verified based on compliance with a driving criterion developed using a dynamic method (see Articles 10.7.3.8.2, 10.7.3.8.3, 10.7.3.8.4, or 10.7.3.8.5). The actual penetration depth where the pile is stopped using the driving criterion (e.g., a blow count measured during pile driving) will likely not be the same as the estimated depth from the static analysis. Hence, the reliability of the nominal pile bearing resistance is dependent on the reliability of the method used to verify the nominal resistance during pile installation (see Allen,

2005, for additional discussion on this issue). Therefore, the resistance factor for the field verification method should be used to determine the number of piles of a given nominal resistance needed to resist the factored loads in the strength limit state.

If the resistance factors provided in Table 10.5.5.2.3-1 are to be applied to small pile groups, the resistance factor values in the table should be reduced by 20 percent to reflect the reduced ability for overstressing of an individual foundation element to be carried by adjacent foundation elements. The minimum size of a pile group necessary to provide significant opportunity for load sharing ranges from 2 or 3 (Isenhower and Long, 1997) to 5 (Paikowsky et al., 2004).

The ability to share load between structural elements should an overstress occur is addressed in Article 1.3.4 through the use of η_R . The values for η_R provided in that Article have been developed in general for the superstructure, and no specific guidance on the application of η_R to foundations is provided. The η_R factor values recommended in Article 1.3.4 are not adequate to address this ability to shed load to other foundation elements when some of the foundation elements become overstressed, based on the results provided by Paikowsky et al. (2004) and others (see also Allen, 2005). Therefore, the resistance factors specified in Table 10.5.5.2.3-1 should be reduced based on the guidance provided in this Article to account for the lack of load sharing opportunities due to the small pile group size.

Dynamic methods may underpredict the nominal axial resistance of piles driven in soft silts or clays where a large amount of setup is anticipated and it is not feasible to perform static load or dynamic tests over a sufficient length of time to assess soil setup.

See Allen (2005) for an explanation on the development of the resistance factors for pile foundation design.

For all axial resistance calculation methods, the resistance factors were, in general, developed from load test results obtained on piles with diameters of 24.0 in. or less. Very little data were available for larger diameter piles. Therefore, these resistance factors should be used with caution for design of significantly larger diameter piles. In general, experience has shown that the static analysis methods identified in Table 10.5.5.2.3-1 tend to significantly overestimate the available nominal resistance for larger diameter piles. A static or dynamic load test should be considered if piles larger than 24.0 in. in diameter are anticipated.

Where driving criteria are established based on a static load test, the potential for site variability should be considered. The number of load tests required should be established based on the characterization of site subsurface conditions by the field and laboratory exploration and testing program.

One of the following alternative approaches may be used to address site variability when extrapolating pile

Note that a site as defined herein may be only a portion of the area in which the structure (or structures) is located. For sites where conditions are highly variable, a site could even be limited to a single pier.

load test results, and the application of driving criteria from those load test results, to piles not load tested:

1. Divide up the site into zones where subsurface conditions are relatively uniform using engineering judgment, conducting one static pile load test in each zone, and dynamic testing with signal matching on a minimum of two percent of the production piles, but no less than two production piles. A resistance factor of 0.80 is recommended if this approach is used. If production pile dynamic testing is not conducted, then a resistance factor of 0.75 should be used.
2. Characterize the site variability and select resistance factors using the approach described by Paikowsky et al. (2004).

The dynamic testing with signal matching should be evenly distributed within a pier and across the entire structure. However, within a particular footing, an increase in safety is realized where the most heavily loaded piles are tested.

The resistance factors in Table 10.5.5.2.3-1 for the case where dynamic testing is conducted without static load testing were developed using reliability theory for beginning of redrive (BOR) conditions. These resistance factors may be used for end of driving (EOD) conditions, but it should be recognized that dynamic testing with signal matching at EOD will likely produce conservative results because soil set up, which causes nominal pile bearing resistance to increase, is not taken into account. If, instead, relaxation is anticipated to occur, these resistance factors for dynamic testing should only be used at BOR.

The 0.50 resistance factor in Table 10.5.5.2.3-1 for use of the wave equation without dynamic measurements to estimate nominal pile bearing resistance is based on calibration by fitting to past ASD practice. Using default wave equation hammer and soil input values, reliability theory calibrations performed by Paikowsky et al. (2004) suggest that a resistance factor of 0.40 should be used if the wave equation is used to estimate nominal pile bearing resistance. Their recommendation is more conservative than the resistance factor implied by past ASD practice. Their recommendation should be considered representative of the reliability of the wave equation to estimate nominal pile bearing resistance by designers who lack experience with the wave equation and its application to local or regional subsurface conditions. Application of default wave equation input parameters without consideration to local site conditions and observed hammer performance in combination with this lower resistance factor is not recommended.

Local experience or site-specific test results should be used to refine the wave equation soil input values, or to at least use the input values selected with greater confidence, and field verification of the hammer performance should be conducted to justify the use of the resistance factor of 0.50 provided in Table 10.5.5.2.3-1. Field verification of

hammer performance is considered to be a direct measurement of either stroke or kinetic energy.

See Articles 10.7.3.8.2, 10.7.3.8.3, 10.7.3.8.4, and 10.7.3.8.5 for additional guidance regarding static pile load testing, dynamic testing and signal matching, wave equation analysis, and dynamic formulas, respectively, as they apply to the resistance factors provided in Table 10.5.5.2.3-1.

The dynamic pile formulas, i.e., FHWA-modified Gates and *Engineering News* (EN), identified in Table 10.5.5.2.3-1, require the pile hammer energy as an input parameter. The developed hammer energy should be used for this purpose, defined as the product of actual stroke developed during the driving of the pile (or equivalent stroke as determined from the bounce chamber pressure for double acting hammers) and the hammer ram weight.

The resistance factors provided in Table 10.5.5.2.3-1 are specifically applicable to the dynamic pile formula as provided in Article 10.7.3.8.5. Note that for the EN formula, the built-in safety factor of 6 has been removed so that it predicts nominal resistance. Therefore, the resistance factor shown in Table 10.5.5.2.3-1 for EN formula should not be applied to the traditional “allowable stress” form of the equation.

The resistance factors for the dynamic pile formulas, i.e., FHWA-modified Gates and EN, in Table 10.5.5.2.3-1 have been specifically developed for EOD conditions. Since static pile load test data, which include the effects of soil setup or relaxation (for the database used, primarily soil setup), were used to develop the resistance factors for these formulas, the resistance factors reflect soil setup occurring after the pile installation. At BOR, the blow count obtained already includes the soil setup. Therefore, a lower resistance factor for the driving formulas should be used for BOR conditions than the ones shown in Table 10.5.5.2.3-1 for EOD conditions. In general, dynamic testing should be conducted to verify nominal pile resistance at BOR in lieu of the use of driving formulas.

Paikowsky et al. (2004) indicate that the resistance factors for static pile resistance analysis methods can vary significantly for different pile types. The resistance factors presented are average values for the method. See Allen (2005) for additional information regarding this issue.

The resistance factor for the Nordlund/Thurman method was derived primarily using the Peck et al. (1974) correlation between SPT N_{60} and the soil friction angle, using a maximum design soil friction angle of 36 degrees, assuming the contributing zone for the bearing resistance is from the tip to two pile diameters below the tip. These assumptions should be considered when using the resistance factor specified in Table 10.5.5.2.3-1 for this static analysis method.

For the clay static pile analysis methods, if the soil cohesion was not measured in the laboratory, the correlation between SPT N and S_u by Hara et al. (1974) was used for the calibration. Use of other methods to

estimate S_u may require the development of resistance factors based on those methods.

The resistance factors provided for uplift of single piles are generally less than the resistance factors for axial side resistance under compressive loading. This is consistent with past practice that recognizes the side resistance in uplift is generally less than the side resistance under compressive loading, and is also consistent with the statistical calibrations performed in Paikowsky et al. (2004). Since the reduction in uplift resistance that occurs in tension relative to the side resistance in compression is taken into account through the resistance factor, the calculation of side resistance using a static pile resistance analysis method should not be reduced from what is calculated from the methods provided in Article 10.7.3.8.6.

For uplift, the number of pile load tests required to justify a specific resistance factor are the same as that required for determining compression resistance. Extrapolating the pile load test results to other untested piles as specified in Article 10.7.3.10 does create some uncertainty, since there is not a way to directly verify that the desired uplift resistance has been obtained for each production pile. This uncertainty has not been quantified. Therefore, it is recommended that a resistance factor of not greater than 0.60 be used if an uplift load test is conducted.

Regarding pile drivability analysis, the only source of load is from the pile driving hammer. Therefore, the load factors provided in Section 3 do not apply. In past practice, e.g., AASHTO (2002), no load factors were applied to the stresses imparted to the pile top by the pile hammer. Therefore, a load factor of 1.0 should be used for this type of analysis. Generally, either a wave equation analysis or dynamic testing, or both, are used to determine the stresses in the pile resulting from hammer impact forces. See Article 10.7.8 for the specific calculation of the pile structural resistance available for analysis of pile drivability. The structural resistance available during driving determined as specified in Article 10.7.8 considers the ability of the pile to handle the transient stresses resulting from hammer impact, considering variations in the materials, pile/hammer misalignment, and variations in the pile straightness and uniformity of the pile head impact surface.

Table 10.5.5.2.3-1—Resistance Factors for Driven Piles

	Condition/Resistance Determination Method	Resistance Factor
Nominal Bearing Resistance of Single Pile—Dynamic Analysis and Static Load Test Methods, ϕ_{dyn}	Driving criteria established by successful static load test of at least one pile per site condition and dynamic testing* of at least two piles per site condition, but no less than 2% of the production piles	0.80
	Driving criteria established by successful static load test of at least one pile per site condition without dynamic testing	0.75
	Driving criteria established by dynamic testing* conducted on 100% of production piles	0.75
	Driving criteria established by dynamic testing*, quality control by dynamic testing* of at least two piles per site condition, but no less than 2% of the production piles	0.65
	Wave equation analysis, without pile dynamic measurements or load test but with field confirmation of hammer performance	0.50
	FHWA-modified Gates dynamic pile formula (EOD condition only)	0.40
	EN (as defined in Article 10.7.3.8.5) dynamic pile formula (EOD condition only)	0.10
Nominal Bearing Resistance of Single Pile—Static Analysis Methods, ϕ_{stat}	Side Resistance and End Bearing: Clay and Mixed Soils α -method (Tomlinson, 1987; Skempton, 1951)	0.35
	β -method (Esrig and Kirby, 1979; Skempton, 1951)	0.25
	λ -method (Vijayvergiya and Focht, 1972; Skempton, 1951)	0.40
	Side Resistance and End Bearing: Sand Nordlund/Thurman Method (Hannigan et al., 2006)	0.45
	SPT-method (Meyerhof)	0.30
	CPT-method (Schmertmann, 1970)	0.50
Block Failure, ϕ_{bl}	End bearing in rock (Canadian Geotech. Society, 1985)	0.45
	Clay	0.60
Uplift Resistance of Single Piles, ϕ_{up}	Nordlund Method	0.35
	α -method	0.25
	β -method	0.20
	λ -method	0.30
	SPT-method	0.25
	CPT-method	0.40
	Static load test	0.60
Group Uplift Resistance, ϕ_{ug}	Dynamic test with signal matching	0.50
	All soils	0.50
Lateral Geotechnical Resistance of Single Pile or Pile Group	All soils and rock	1.0
Structural Limit State	Steel piles	See the provisions of Article 6.5.4.2
	Concrete piles	See the provisions of Article 5.5.4.2
	Timber piles	See the provisions of Articles 8.5.2.2 and 8.5.2.3
Pile Drivability Analysis, ϕ_{da}	Steel piles	See the provisions of Article 6.5.4.2
	Concrete piles	See the provisions of Article 5.5.4.2
	Timber piles	See the provisions of Article 8.5.2.2
	In all three Articles identified above, use ϕ identified as “resistance during pile driving”	

*Dynamic testing requires signal matching, and best estimates of nominal resistance are made from a restrike. Dynamic tests are calibrated to the static load test, when available.

10.5.5.2.4—Drilled Shafts

Resistance factors shall be selected based on the method used for determining the nominal shaft resistance. When selecting a resistance factor for shafts in clays or other easily disturbed formations, local experience with the geologic formations and with typical shaft construction practices shall be considered.

Where the resistance factors provided in Table 10.5.5.2.4-1 are to be applied to a single shaft supporting a bridge pier, the resistance factor values in the Table should be reduced by 20 percent. Where the resistance factor is decreased in this manner, the η_R factor provided in Article 1.3.4 shall not be increased to address the lack of foundation redundancy.

The number of static load tests to be conducted to justify the resistance factors provided in Table 10.5.5.2.4-1 shall be based on the variability in the properties and geologic stratification of the site to which the test results are to be applied. A site, for the purpose of assessing variability, shall be defined as a project site, or a portion of it, where the subsurface conditions can be characterized as geologically similar in terms of subsurface stratification; i.e., sequence, thickness, and geologic history of strata, the engineering properties of the strata, and groundwater conditions.

C10.5.5.2.4

The resistance factors in Table 10.5.5.2.4-1 were developed using either statistical analysis of shaft load tests combined with reliability theory (Paikowsky et al., 2004), fitting to ASD, or both. Where the two approaches resulted in a significantly different resistance factor, engineering judgment was used to establish the final resistance factor, considering the quality and quantity of the available data used in the calibration. The available reliability theory calibrations were conducted for the Reese and O'Neill (1988) method, with the exception of shafts in intermediate geomaterials (IGMs), in which case the O'Neill and Reese (1999) method was used. In Article 10.8, the O'Neill and Reese (1999) method is recommended. See Allen (2005) for a more detailed explanation on the development of the resistance factors for shaft foundation design, and the implications of the differences in these two shaft design methods on the selection of resistance factors.

For single shafts, lower resistance factors are specified to address the lack of redundancy. See Article C10.5.5.2.3 regarding the use of η_R .

Where installation criteria are established based on one or more static load tests, the potential for site variability should be considered. The number of load tests required should be established based on the characterization of site subsurface conditions by the field and laboratory exploration and testing program. One or more static load tests should be performed per site to justify the resistance factor selection.

Site variability is the most important consideration in evaluating the limits of a site for design purposes. Defining the limits of a site therefore requires sufficient knowledge of the subsurface conditions in terms of general geology, stratigraphy, index and engineering properties of soil and rock, and groundwater conditions. This implies that the extent of the exploration program is sufficient to define the subsurface conditions and their variation across the site.

A Designer may choose to design drilled shaft foundations for strength limit states based on a calculated nominal resistance, with the expectation that load testing results will verify that value. The question arises whether to use the resistance factor associated with the design equation or the higher value allowed for load testing. This choice should be based on engineering judgment. The potential risk is that axial resistance measured by load testing may be lower than the nominal resistance used for design, which could require increased shaft dimensions that may be problematic, depending on the capability of the drilled shaft equipment mobilized for the project and other project-specific factors.

For the specific case of shafts in clay, the resistance factor recommended by Paikowsky et al. (2004) is much lower than the recommendation from Barker et al. (1991). Since the shaft design method for clay is nearly the same for both the 1988 and 1999 methods, a resistance factor that represents the average of the two resistance factor

recommendations is provided in Table 10.5.5.2.4-1. This difference may point to the differences in local geologic formations and local construction practices, pointing to the importance of taking such issues into consideration when selecting resistance factors, especially for shafts in clay.

Cohesive IGMs are materials that are transitional between soil and rock in terms of their strength and compressibility, such as clay shales or mudstones with undrained shear strength between 5 and 50 ksf.

Since the mobilization of shaft base resistance is less certain than side resistance due to the greater deformation required to mobilize the base resistance, a lower resistance factor relative to the side resistance is provided for the base resistance in Table 10.5.5.2.4-1. O'Neill and Reese (1999) make further comment that the recommended resistance factor for tip resistance in sand is applicable for conditions of high quality control on the properties of drilling slurries and base cleanout procedures. If high quality control procedures are not used, the resistance factor for the O'Neill and Reese (1999) method for tip resistance in sand should be also be reduced. The amount of reduction should be based on engineering judgment.

Shaft compression load test data should be extrapolated to production shafts that are not load tested as specified in Article 10.8.3.5.6. There is no way to verify shaft resistance for the untested production shafts, other than through good construction inspection and visual observation of the soil or rock encountered in each shaft. Because of this, extrapolation of the shaft load test results to the untested production shafts may introduce some uncertainty. Statistical data are not available to quantify this at this time. Historically, resistance factors higher than 0.70, or their equivalent safety factor in previous practice, have not been used for shaft foundations. If the recommendations in Paikowsky et al. (2004) are used to establish a resistance factor when shaft static load tests are conducted, in consideration of site variability, the resistance factors recommended by Paikowsky et al. for this case should be reduced by 0.05, and should be less than or equal to 0.70 as specified in Table 10.5.5.2.4-1.

This issue of uncertainty in how the load test is applied to shafts not load tested is even more acute for shafts subjected to uplift load tests, as failure in uplift can be more abrupt than failure in compression. Hence, a resistance factor of 0.60 for the use of uplift load test results is recommended.

Table 10.5.5.2.4-1—Resistance Factors for Geotechnical Resistance of Drilled Shafts

Method/Soil/Condition			Resistance Factor
Nominal Axial Compressive Resistance of Single-Drilled Shafts, ϕ_{stat}	Side resistance in clay	α -method (Brown et al., 2010)	0.45
	Tip resistance in clay	Total Stress (Brown et al., 2010)	0.40
	Side resistance in sand	β -method (Brown et al., 2010)	0.55
	Tip resistance in sand	Brown et al. (2010)	0.50
	Side resistance in cohesive IGMs	Brown et al. (2010)	0.60
	Tip resistance in cohesive IGMs	Brown et al. (2010)	0.55
	Side resistance in rock	Kulhawy et al. (2005) Brown et al. (2010)	0.55
	Side resistance in rock	Carter and Kulhawy (1988)	0.50
	Tip resistance in rock	Canadian Geotechnical Society (1985) Pressuremeter Method (Canadian Geotechnical Society, 1985) Brown et al. (2010)	0.50
Block Failure, ϕ_{b1}	Clay		0.55
Uplift Resistance of Single-Drilled Shafts, ϕ_{up}	Clay	α -method (Brown et al., 2010)	0.35
	Sand	β -method (Brown et al., 2010)	0.45
	Rock	Kulhawy et al. (2005) Brown et al. (2010)	0.40
Group Uplift Resistance, ϕ_{ug}	Sand and clay		0.45
Horizontal Geotechnical Resistance of Single Shaft or Shaft Group	All materials		1.0
Static Load Test (compression), ϕ_{load}	All Materials		0.70
Static Load Test (uplift), ϕ_{upload}	All Materials		0.60

10.5.5.2.5—Micropiles

Resistance factors shall be selected from Table 10.5.5.2.5-1 based on the method used for determining the nominal axial pile resistance. If the resistance factors provided in Table 10.5.5.2.5-1 are to be applied to piles in potentially creeping soils, highly plastic soils, weak rock, or other marginal ground type, the resistance factor values in the Table should be reduced by 20 percent to reflect greater design uncertainty.

C10.5.5.2.5

The resistance factors in Table 10.5.5.2.5-1 were calibrated by fitting to ASD procedures tempered with engineering judgment. The resistance factors in Table 10.5.5.2.5-2 for structural resistance were calibrated by fitting to ASD procedures and are equal to or slightly more conservative than corresponding resistance factors from Section 5 for reinforced concrete column design.

10.6—SPREAD FOOTINGS

10.6.1—General Considerations

10.6.1.1—General

Provisions of this Article shall apply to design of isolated, continuous strip and combined footings for use in support of columns, walls and other substructure and superstructure elements. Special attention shall be given to footings on fill, to make sure that the quality of the fill placed below the footing is well controlled and of adequate quality in terms of shear strength and compressibility to support the footing loads.

Spread footings shall be proportioned and designed such that the supporting soil or rock provides adequate nominal resistance, considering both the potential for adequate bearing strength and the potential for settlement, under all applicable limit states in accordance with the provisions of this Section.

Spread footings shall be proportioned and located to maintain stability under all applicable limit states, considering the potential for, but not necessarily limited to, overturning (eccentricity), sliding, uplift, overall stability and loss of lateral support.

10.6.1.2—Bearing Depth

Where the potential for scour, erosion or undermining exists, shallow foundations (i.e., spread footings) shall be located such that the top of the footing is located at or below the maximum anticipated depth of scour from the scour check flood, erosion, or undermining as specified in Article 2.6.4.4.3.

Spread footings shall be located below the depth of frost potential. The depth of frost potential shall be determined on the basis of local or regional frost penetration data.

C10.6.1.1

Problems with insufficient bearing and/or excessive settlements in fill can be significant, particularly if poor, e.g., soft, wet, frozen, or nondurable, material is used, or if the material is not properly compacted.

Spread footings should not be used on soil or rock conditions that are determined to be too soft or weak to support the design loads without excessive movement or loss of stability. Alternatively, the unsuitable material can be removed and replaced with suitable and properly compacted engineered fill material, or improved in place, at reasonable cost as compared to other foundation support alternatives.

Footings should be proportioned so that the stress under the footing is as nearly uniform as practicable at the service limit state. The distribution of soil stress should be consistent with properties of the soil or rock and the structure and with established principles of soil and rock mechanics.

C10.6.1.2

Consideration should be given to the use of either a geotextile or graded granular filter material to reduce the susceptibility of fine-grained material piping into rip rap or open-graded granular foundation material.

For spread footings founded on excavated or blasted rock, attention should be paid to the effect of excavation and/or blasting. Blasting of highly resistant competent rock formations may result in overbreak and fracturing of the rock to some depth below the bearing elevation. Blasting may reduce the resistance to scour within the zone of overbreak or fracturing. See Article 10.4.6.6 regarding factors affecting erodibility of rock.

Evaluation of seepage forces and hydraulic gradients should be performed as part of the design of foundations that will extend below the groundwater table. Upward seepage forces in the bottom of excavations can result in piping loss of soil and/or heaving and loss of stability in the base of foundation excavations. Dewatering with wells or wellpoints can control these problems. Dewatering can result in settlement of adjacent ground or structures. If adjacent structures may be damaged by settlement induced by dewatering, seepage cut-off methods such as sheet piling or slurry walls may be necessary.

Consideration may be given to over-excavation of frost susceptible material to below the frost depth and replacement with material that is not frost susceptible.

10.6.1.3—Effective Footing Dimensions

For eccentrically loaded footings, a reduced effective area, $B' \times L'$, within the confines of the physical footing shall be used in geotechnical design for settlement or bearing resistance. The point of load application shall be at the centroid of the reduced effective area.

The reduced dimensions for an eccentrically loaded rectangular footing shall be taken as:

$$B' = B - 2e_B \quad (10.6.1.3-1)$$

$$L' = L - 2e_L$$

where:

e_B = eccentricity parallel to dimension B (ft)

e_L = eccentricity parallel to dimension L (ft)

Footings under eccentric loads shall be designed to ensure that the factored bearing resistance is not less than the effects of factored loads at all applicable limit states.

For footings that are not rectangular, similar procedures should be used based upon the principles specified above.

10.6.1.4—Bearing Stress Distributions

When proportioning footing dimensions to meet settlement and bearing resistance requirements at all applicable limit states, the distribution of bearing stress on the effective area shall be assumed to be:

- uniform for footings on soils; or
- linearly varying, i.e., triangular or trapezoidal as applicable, for footings on rock.

The distribution of bearing stress shall be determined as specified in Article 11.6.3.2.

Bearing stress distributions for structural design of the footing shall be as specified in Article 10.6.5.

C10.6.1.3

The reduced dimensions for a rectangular footing are shown in Figure C10.6.1.3-1.

Figure C10.6.1.3-1—Reduced Footing Dimensions

For footings that are not rectangular, such as the circular footing shown in Figure C10.6.1.3-1, the reduced effective area is always concentrically loaded and can be estimated by approximation and judgment. Such an approximation could be made, assuming a reduced rectangular footing size having the same area and centroid as the shaded area of the circular footing shown in Figure C10.6.1.3-1.

10.6.1.5—Anchorage of Inclined Footings

Footings that are founded on inclined smooth solid rock surfaces and that are not restrained by an overburden of resistant material shall be effectively anchored by means of rock anchors, rock bolts, dowels, keys, or other suitable means. Shallow keying of large footings shall be avoided where blasting is required for rock removal.

10.6.1.6—Groundwater

Spread footings shall be designed in consideration of the highest anticipated groundwater table.

The influences of groundwater table on the bearing resistance of soils or rock and on the settlement of the structure shall be considered. In cases where seepage forces are present, they should also be included in the analyses.

10.6.1.7—Uplift

Where spread footings are subjected to uplift forces, they shall be investigated both for resistance to uplift and for structural strength.

10.6.1.8—Nearby Structures

Where foundations are placed adjacent to existing structures, the influence of the existing structure on the behavior of the foundation and the effect of the foundation on the existing structures shall be investigated.

10.6.2—Service Limit State Design**10.6.2.1—General**

Service limit state design of spread footings shall include evaluation of total and differential settlement.

10.6.2.2—Tolerable Movements

The requirements of Article 10.5.2.1 shall apply.

10.6.2.3—Loads

Immediate settlement shall be determined using load combination Service I, as specified in Table 3.4.1-1. Time-dependent settlements in cohesive soils should be determined using only the permanent loads, i.e., transient loads should not be considered.

C10.6.1.5

Design of anchorages should include consideration of corrosion potential and protection.

C10.6.2.1

The design of spread footings is frequently controlled by movement at the service limit state. It is therefore usually advantageous to proportion spread footings at the service limit state and check for adequate design at the strength and extreme limit states.

C10.6.2.3

The type of load or the load characteristics may have a significant effect on spread footing deformation. The following factors should be considered in the estimation of footing deformation:

- The ratio of sustained load to total load;
- The duration of sustained loads; and
- The time interval over which settlement or lateral displacement occurs.

10.6.2.4—Settlement Analyses

10.6.2.4.1—General

Foundation settlements should be estimated using computational methods based on the results of laboratory or insitu testing, or both. The soil parameters used in the computations should be chosen to reflect the loading history of the ground, the construction sequence, and the effects of soil layering.

Both total and differential settlements, including time dependent effects, shall be considered.

Total settlement, including elastic, consolidation, and secondary components may be taken as:

$$S_t = S_e + S_c + S_s \quad (10.6.2.4.1-1)$$

where:

S_e = elastic settlement (ft)

S_c = primary consolidation settlement (ft)

S_s = secondary settlement (ft)

The consolidation settlements in cohesive soils are time-dependent; consequently, transient loads have negligible effect. However, in cohesionless soils where the permeability is sufficiently high, elastic deformation of the supporting soil due to transient load can take place. Because deformation in cohesionless soils often takes place during construction while the loads are being applied, it can be accommodated by the structure to an extent, depending on the type of structure and construction method.

Deformation in cohesionless, or granular, soils often occurs as soon as loads are applied. As a consequence, settlements due to transient loads may be significant in cohesionless soils, and they should be included in settlement analyses.

C10.6.2.4.1

Elastic, or immediate, settlement is the instantaneous deformation of the soil mass that occurs as the soil is loaded. The magnitude of elastic settlement is estimated as a function of the applied stress beneath a footing or embankment. Elastic settlement is usually small and neglected in design, but where settlement is critical, it is the most important deformation consideration in cohesionless soil deposits and for footings bearing on rock. For footings located on over-consolidated clays, the magnitude of elastic settlement is not necessarily small and should be checked.

In a nearly saturated or saturated cohesive soil, the pore water pressure initially carries the applied stress. As pore water is forced from the voids in the soil by the applied load, the load is transferred to the soil skeleton. Consolidation settlement is the gradual compression of the soil skeleton as the pore water is forced from the voids in the soil. Consolidation settlement is the most important deformation consideration in cohesive soil deposits that possess sufficient strength to safely support a spread footing. While consolidation settlement can occur in saturated cohesionless soils, the consolidation occurs quickly and is normally not distinguishable from the elastic settlement.

Secondary settlement, or creep, occurs as a result of the plastic deformation of the soil skeleton under a constant effective stress. Secondary settlement is of principal concern in highly plastic or organic soil deposits. Such deposits are normally so obviously weak and soft as to preclude consideration of bearing a spread footing on such materials.

The principal deformation component for footings on rock is elastic settlement, unless the rock or included discontinuities exhibit noticeable time-dependent behavior.

To avoid overestimation, relevant settlements should be evaluated using the construction-point concept described in Samtani et al. (2010).

The effects of the zone of stress influence, or vertical stress distribution, beneath a footing shall be considered in estimating the settlement of the footing.

Spread footings bearing on a layered profile consisting of a combination of cohesive soil, cohesionless soil and/or rock shall be evaluated using an appropriate settlement estimation procedure for each layer within the zone of influence of induced stress beneath the footing.

Unless otherwise specified for a specific settlement estimation method, the distribution of vertical stress increase below circular or square and long rectangular footings, i.e., where $L > 5B$, may be estimated using Figure 10.6.2.4.1-1.

For guidance on vertical stress distribution for complex footing geometries, see Poulos and Davis (1974) or Lambe and Whitman (1969).

Some methods used for estimating settlement of footings on sand include an integral method to account for the effects of vertical stress increase variations. For guidance regarding application of these procedures, see Gifford et al. (1987) and Samtani and Nowatzki (2006).

Figure 10.6.2.4.1-1—Boussinesq Vertical Stress Contours for Continuous and Square Footings Modified after Sowers (1979)

10.6.2.4.2—Settlement of Footings on Cohesionless Soils

10.6.2.4.2a—General

The settlement of spread footings bearing on cohesionless soil deposits shall be estimated as a function of effective footing width and shall consider the effects of footing geometry and soil and rock layering with depth.

C10.6.2.4.2a

For general guidance regarding the estimation of elastic settlement of footings on cohesionless soils, see Gifford et al. (1987), and Kimmerling (2002), and Samtani and Nowatzki (2006).

Although methods are recommended for the determination of settlement of cohesionless soils, experience has indicated that settlements can vary considerably in a construction site, and this variation may not be predicted by conventional calculations.

Settlements of cohesionless soils occur rapidly, essentially as soon as the foundation is loaded. Therefore, the total settlement under the service loads may not be as important as the incremental settlement between intermediate load stages. For example, the total and

Settlements of footings on cohesionless soils shall be estimated using elastic theory or calibrated empirical procedures.

differential settlement- due to loads applied by columns and cross beams is generally less important than the total and differential settlements due to girder placement and casting of continuous concrete decks.

The stress distributions used to calculate elastic settlement assume the footing is flexible and supported on a homogeneous soil of infinite depth. The settlement below a flexible footing varies from a maximum near the center to a minimum at the edge equal to about 50 percent and 64 percent of the maximum for rectangular and circular footings, respectively. The settlement profile for rigid footings is assumed to be uniform across the width of the footing.

Spread footings of the dimensions normally used for bridges are generally assumed to be rigid, although the actual performance will be somewhere between perfectly rigid and perfectly flexible, even for relatively thick concrete footings, due to stress redistribution and concrete creep.

Generally conservative settlement estimates may be obtained using the empirical methods by Hough and Schmertmann. Additional information regarding the accuracy of the methods described herein is provided in Gifford et al. (1987) and Kimmerling (2002), Samtani and Nowatzki (2006), and Samtani and Allen (2018). This information, in combination with local experience and engineering judgment, should be used when determining the estimated settlement for a structure foundation, as there may be cases, such as attempting to build a structure grade high to account for the estimated settlement, when overestimating the settlement magnitude could be problematic. Samtani and Allen (2018) found that soil settlement estimation using these methods does not provide meaningful results for estimated settlements of less than 0.5 in. Therefore, assessment of the angular distortions and associated force effects such as shear and moment in a structure resulting from differential settlement within or between foundation elements should not depend on the ability to predict a foundation settlement of less than 0.5 in. Hence, in cases where the estimated total settlement of footings on soil is less than 0.5 in., a minimum differential settlement of 0.5 in. should be assumed for calculating the angular distortions and associated force effects for structural analysis.

If the structure foundation is located in or adjacent to a bridge approach fill or reinforced soil structure, settlement due the fill or reinforced soil structure should be included in the footing settlement estimate, unless the approach fill or reinforced soil structure settlement is allowed to occur before the bridge foundation is constructed. Both the Hough and Schmertmann methods have been successfully used to estimate fill/reinforced soil structure settlement when cohesionless soils are present (Samtani and Allen, 2018).

Details of other settlement estimation procedures can be found in textbooks and engineering manuals, including:

- Terzaghi and Peck (1967)
- Sowers (1979)
- U.S. Department of the Navy (1982)
- Gifford et al. (1987)—This method includes consideration for over-consolidated sands.
- Tomlinson (1986)
- Elastic Half Space Method (Munkfakh et al., 2001)

Use of methods based on local geologic conditions and calibration require approval from the Owner.

These methods, however, have not been calibrated.

Calibration of local methods should be based on processes as described in Samtani and Kulicki (2018) and Samtani and Allen (2018).

10.6.2.4.2b—Hough Method

Estimation of spread footing settlement on cohesionless soils by the empirical Hough method shall be determined using Eqs. 10.6.2.4.2b-1 and 10.6.2.4.2b-2. SPT blow counts shall be corrected as specified in Article 10.4.6.2.4 for depth, i.e. overburden stress, and SPT hammer efficiency, before correlating the SPT blow counts to the bearing capacity index, C' .

$$S_e = \sum_{i=1}^n \Delta H_i \quad (10.6.2.4.2b-1)$$

in which:

$$\Delta H_i = H_c \frac{1}{C'} \log \left(\frac{\sigma'_o + \Delta \sigma_v}{\sigma'_o} \right) \quad (10.6.2.4.2b-2)$$

where:

- n = number of soil layers within zone of stress influence of the footing
- ΔH_i = elastic settlement of layer i (ft)
- H_c = initial height of layer i (ft)
- C' = bearing capacity index from Figure 10.6.2.4.2b-1 (dim)
- σ'_o = initial vertical effective stress at the midpoint of layer i (ksf)
- $\Delta \sigma_v$ = increase in vertical stress at the midpoint of layer i (ksf)

C10.6.2.4.2b

The Hough method was developed for normally consolidated cohesionless soils.

The Hough method has several advantages over other methods used to estimate settlement in cohesionless soil deposits, including express consideration of soil layering and the zone of stress influence beneath a footing of finite size.

The subsurface soil profile should be subdivided into layers based on stratigraphy to a depth of about three times the footing width. The maximum layer thickness should be about 10.0 ft.

While Hough (1959) did not specifically state that the SPT N values should be corrected for hammer energy in addition to overburden pressure, due to the vintage of the original work, hammers that typically have an efficiency of approximately 60 percent were in general used to develop the empirical correlations contained in the method. If using SPT hammers with efficiencies that differ significantly from this 60 percent value, the N values should also be corrected for hammer energy, in effect requiring that N_{160} be used (Samtani and Nowatzki, 2006).

Studies conducted by Gifford et al. (1987) and Samtani and Nowatzki (2006) indicate that Hough's procedure may be more conservative, but with less prediction variability, than the Schmertmann Method. However, this difference is mostly taken into account through the load factor, γ_{SE} , since it has been calibrated using reliability theory (Kulicki et al. 2015) (Samtani and Kulicki, 2018) (Samtani and Allen (2018).

Figure 10.6.2.4b-1—Bearing Capacity Index versus Corrected SPT (Hough, 1959, as modified in Samtani and Nowatzki, 2006)

10.6.2.4.2c—Schmertmann Method

Estimation of spread footing immediate, or elastic, settlement, S_i , on cohesionless soils by the empirical Schmertmann, method shall be calculated using Eq. 10.6.2.4.2c-1.

$$S_i = C_1 C_2 \Delta p \sum_{i=1}^n \Delta J_i \quad (10.6.2.4.2c-1)$$

in which:

$$\Delta J_i = H_c \left(\frac{I_z}{144XE} \right) \quad (10.6.2.4.2c-2)$$

$$C_1 = 1 - 0.5 \left(\frac{p_o}{\Delta p} \right) \geq 0.5 \quad (10.6.2.4.2c-3)$$

$$C_2 = 1 + 0.2 \log_{10} \left(\frac{t}{0.1} \right) \quad (10.6.2.4.2c-4)$$

where:

ΔJ_i = elastic spring stiffness of layer, i (ft/ksf)
 H_c = height of compressible soil layer, i (ft)
 I_z = strain influence factor from Figure 10.6.2.4.2c-1a. The dimensions L_f and B_f represent the least lateral dimension of the footing after correction for eccentricities, i.e., use effective footing dimension. The strain influence factor is a function of depth and is obtained from the strain influence diagram. The strain influence diagram is constructed for the

The Hough method is applicable to cohesionless soil deposits. The “Inorganic Silt” curve should generally not be applied to soils that exhibit plasticity because N -values in such soils are unreliable (Samtani and Nowatzki, 2006). The settlement characteristics of cohesive soils that exhibit plasticity should be investigated using undisturbed samples and laboratory consolidation tests as prescribed in Article 10.6.2.4.3.

C10.6.2.4.2c

Background information for this method, originally published in Schmertmann (1970) and Schmertmann et al. (1978), in the format as presented here can be found in Samtani and Nowatzki (2006). This method was originally developed for use with the static cone bearing resistance q_c , in which q_c was correlated to the soil modulus, E , and E is used directly in this method. The original formulation for this correlation by Schmertmann (1970) assumed E was in units of tsf (i.e., E (in tsf) = $2q_c$ (in tsf or kg/cm²)). The correlation in Table 10.6.2.4.2c-1 predicts E in ksi. Correlations between E and the SPT N values are also available and provided in Table 10.6.2.4.2c-1.

The variables in the equation for ΔJ_i (Eq. 10.6.2.4.2c-2) require specific units for H_c (ft) and E (provided in Table 10.6.2.4.2c-1) is in ksi. This results in the units for ΔJ_i being ft/ksf. Furthermore, in Eqs. 10.6.2.4.2c-1 and 10.6.2.4.2c-3, units of p_o and Δp must be ksf.

axisymmetric case ($L_f/B_f = 1$) and the plane strain case ($L_f/B_f \geq 10$) as shown in Figure 10.6.2.4.2c-1a. The strain influence diagram for intermediate conditions should be determined by simple linear interpolation.

- n = number of soil layers within the zone of strain influence (strain influence diagram).
- Δp = net uniform applied stress (load intensity) at the foundation depth as shown in Figure 10.6.2.4.2c-1b, in which p is equal to the uniform applied footing stress, σ_v , as specified in Article 11.6.3.2 (see Figure 10.6.2.4.2c-1b) (ksf).
- E = elastic modulus of layer i , estimated using Table 10.6.2.4.2c-1 (ksi).
- X = a factor used to determine the value of elastic modulus. The value of elastic modulus is based on correlations with N_{160} -values or q_c from Table 10.6.2.4.2c-1, then values of X shall be taken as follows:

$X = 1.25$ for axisymmetric case ($L_f/B_f = 1$)

$X = 1.75$ for plane strain case ($L_f/B_f \geq 10$)

Use interpolation for footings with values of L_f/B_f between 1 and 10. If the value of elastic modulus is based on in-situ testing (e.g., pressuremeter), use $X = 1.0$.

- C_1 = correction factor to incorporate the effect of strain relief due to embedment
- p_o = effective in-situ overburden stress at the foundation depth as shown in Figure 10.6.2.4.2c-1b (ksf)
- p_{op} = effective in-situ overburden stress at the depth to peak strain influence factor, I_{sp} , as shown in Figure 10.6.2.4.2c-1b (ksf)
- Δp = net uniform applied stress (load intensity) at the foundation depth as shown in Figure 10.6.2.4.2c-1b, in which p is equal to the uniform applied footing stress, σ_v , as specified in Article 11.6.3.2 (ksf).
- C_2 = correction factor to incorporate time-dependent (creep) increase in settlement for time, t , after construction
- t = time from completion of construction to date under consideration for evaluation of C_2 (yrs)

The C_2 parameter shall not be used to estimate time-dependent consolidation settlements. Where consolidation settlement can occur within the depth of the strain distribution diagram, the magnitude of the consolidation settlement shall be estimated as per Article 10.6.2.4.3 and added to the immediate settlement of other layers within the strain distribution diagram where consolidation settlement may not occur.

For C_2 , the correction factor, the time duration, t , in Eq. 10.6.2.4.2c-4 is set to 0.1 years to evaluate the settlement immediately after construction, i.e., $C_2 = 1$. If long-term creep movement of the soil is suspected then an appropriate time duration, t , should be used in the computation of C_2 . Creep movement is not the same as consolidation settlement. This factor can have an important influence on the reported settlement since it is included in Eq. 10.6.2.4.2c-1 as a multiplier. For example, the C_2 factor for time durations of 0.1 yrs, 1 yr, 10 yrs, and 50 yrs are 1.0, 1.2, 1.4, and 1.54, respectively. In cohesionless soils and unsaturated fine-grained cohesive soils with low plasticity, time durations of 0.1 yr and 1 yr, respectively, are generally appropriate and sufficient for cases of static loads.

Table 10.6.2.4.2c-1—Correlations between Elastic Soil Modulus and SPT N_{160} or static Cone q_c values for the Schmertmann Method (modified after Schmertmann 1970, and Samtani and Nowatzki 2006)

Correlation between E and SPT N_{160} Value	
Soil Type	E (ksi)
Silts, sandy silts, slightly cohesive mixtures	$0.056 N_{160}$
Clean fine to medium sands and slightly silty sands	$0.097 N_{160}$
Coarse sands and sands with little gravel	$0.139 N_{160}$
Sandy gravel and gravels	0.167
	$10.6.2.4.N_{160}$
Correlation between E and q_c (static cone resistance, in ksi)	
Soil Type	E (ksi)
Sandy soils	$0.028 q_c$

Figure 10.6.2.4.2c-1—(a) Simplified vertical strain influence factor distributions, (b) Explanation of pressure terms in equation for I_{zp} (after Schmertmann et al., 1978, as reported in Samtani and Nowatzki, 2006).

10.6.2.4.3—Settlement of Footings on Cohesive Soils

Spread footings in which cohesive soils are located within the zone of stress influence shall be investigated for consolidation settlement. Elastic and secondary settlement shall also be investigated in consideration of the timing and sequence of construction loading and the tolerance of the structure to total and differential movements.

Where laboratory test results are expressed in terms of void ratio, e , the consolidation settlement of footings shall be taken as:

- For overconsolidated soils where $\sigma'_p > \sigma'_o$, as illustrated in Figure 10.6.2.4.3-2:

$$S_c = \left[\frac{H_c}{1 + e_o} \right] \left[C_r \log \left(\frac{\sigma'_p}{\sigma'_o} \right) + C_c \log \left(\frac{\sigma'_f}{\sigma'_p} \right) \right] \quad (10.6.2.4.3-1)$$

- For normally consolidated soils where $\sigma'_p = \sigma'_o$:

$$S_c = \left[\frac{H_c}{1 + e_o} \right] \left[C_c \log \left(\frac{\sigma'_f}{\sigma'_p} \right) \right] \quad (10.6.2.4.3-2)$$

- For underconsolidated soils where $\sigma'_p < \sigma'_o$:

$$S_c = \left[\frac{H_c}{1 + e_o} \right] \left[C_c \log \left(\frac{\sigma'_f}{\sigma'_{pv}} \right) \right] \quad (10.6.2.4.3-3)$$

Where laboratory test results are expressed in terms of vertical strain, ϵ_v , the consolidation settlement of footings shall be taken as:

- For overconsolidated soils where $\sigma'_p > \sigma'_o$, as illustrated in Figure 10.6.2.4.3-2:

$$S_c = H_c \left[C_{re} \log \left(\frac{\sigma'_p}{\sigma'_o} \right) + C_{ce} \log \left(\frac{\sigma'_f}{\sigma'_p} \right) \right] \quad (10.6.2.4.3-4)$$

- For normally consolidated soils where $\sigma'_p = \sigma'_o$:

$$S_c = H_c C_{ce} \log \left(\frac{\sigma'_f}{\sigma'_p} \right) \quad (10.6.2.4.3-5)$$

- For underconsolidated soils where $\sigma'_p < \sigma'_o$:

$$S_c = H_c C_{ce} \log \left(\frac{\sigma'_f}{\sigma'_{pv}} \right) \quad (10.6.2.4.3-6)$$

C10.6.2.4.3

In practice, footings on cohesive soils are most likely founded on overconsolidated clays, and settlements can be estimated using elastic theory (Baguelin et al., 1978), or the tangent modulus method (Janbu; 1963, 1967). Settlements of footings on overconsolidated clay usually occur at approximately one order of magnitude faster than soils without preconsolidation, and it is reasonable to assume that they take place as rapidly as the loads are applied. Infrequently, a layer of cohesive soil may exhibit a preconsolidation stress less than the calculated existing overburden stress. The soil is then said to be underconsolidated because a state of equilibrium has not yet been reached under the applied overburden stress. Such a condition may have been caused by a recent lowering of the groundwater table. In this case, consolidation settlement will occur due to the additional load of the structure and the settlement that is occurring to reach a state of equilibrium. The total consolidation settlement due to these two components can be estimated by Eqs. 10.6.2.4.3-3 or 10.6.2.4.3-6.

Normally consolidated and underconsolidated soils should be considered unsuitable for direct support of spread footings due to the magnitude of potential settlement, the time required for settlement, for low shear strength concerns, or any combination of these design considerations. Preloading or vertical drains may be considered to mitigate these concerns.

To account for the decreasing stress with increased depth below a footing and variations in soil compressibility with depth, the compressible layer should be divided into vertical increments, i.e., typically 5.0 to 10.0 ft for most normal-width footings for highway applications, and the consolidation settlement of each increment analyzed separately. The total value of S_c is the summation of S_c for each increment.

The magnitude of consolidation settlement depends on the consolidation properties of the soil. These properties include the compression and recompression constants, C_c and C_r , or C_{ce} and C_{re} ; the preconsolidation stress, σ'_p ; the current, initial vertical effective stress, σ'_o ; and the final vertical effective stress after application of additional loading, σ'_f . An overconsolidated soil has been subjected to larger stresses in the past than at present. This could be a result of preloading by previously overlying strata, desiccation, groundwater lowering, glacial overriding or an engineered preload. If $\sigma'_o = \sigma'_p$, the soil is normally consolidated. Because the recompression constant is typically about an order of magnitude smaller than the compression constant, an accurate determination of the preconsolidation stress, σ'_p , is needed to make reliable estimates of consolidation settlement.

The reliability of consolidation settlement estimates is also affected by the quality of the consolidation test sample and by the accuracy with which changes in σ'_p with depth are known or estimated. As shown in Figure C10.6.2.4.3-1, the slope of the e or ϵ_v versus $\log$

where:

- H_c = initial height of compressible soil layer (ft)
 e_o = void ratio at initial vertical effective stress (dim)
 C_r = recompression index (dim)
 C_c = compression index (dim)
 C_{rc} = recompression ratio (dim)
 C_{ck} = compression ratio (dim)
 σ'_p = maximum past vertical effective stress in soil at midpoint of soil layer under consideration (ksf)
 σ'_o = initial vertical effective stress in soil at midpoint of soil layer under consideration (ksf)

- σ'_f = final vertical effective stress in soil at midpoint of soil layer under consideration (ksf)
 σ'_{pc} = current vertical effective stress in soil, not including the additional stress due to the footing loads, at midpoint of soil layer under consideration (ksf)

σ'_v curve and the location of σ'_p can be strongly affected by the quality of samples used for the laboratory consolidation tests. In general, the use of poor quality samples will result in an overestimate of consolidation settlement. Typically, the value of σ'_p will vary with depth as shown in Figure C10.6.2.4.3-2. If the variation of σ'_p with depth is unknown, e.g., only one consolidation test was conducted in the soil profile, actual settlements could be higher or lower than the computed value based on a single value of σ'_p .

The cone penetrometer test may be used to improve understanding of both soil layering and variation of σ'_p with depth by correlation to laboratory tests from discrete locations.

Figure C10.6.2.4.3-1—Effects of Sample Quality on Consolidation Test Results, Holtz and Kovacs (1981)

Figure 10.6.2.4.3-1—Typical Consolidation Compression Curve for Overconsolidated Soil: Void Ratio versus Vertical Effective Stress, EPRI (1983)

Figure C10.6.2.4.3-2—Typical Variation of Preconsolidation Stress with Depth, Holtz and Kovacs (1981)

$$t = \frac{TH_d^2}{c_v} \quad (10.6.2.4.3-8)$$

where:

- T = time factor, taken as specified in Figure 10.6.2.4.3-4 for the excess pore pressure distributions shown in the Figure (dim)
- H_d = length of longest drainage path in compressible layer under consideration (ft)
- c_v = coefficient of consolidation (ft²/yr)

Figure 10.6.2.4.3-4 Percentage of Consolidation as a Function of Time Factor, T (EPRI, 1983)

Where laboratory test results are expressed in terms of void ratio, e , the secondary settlement of footings on cohesive soil shall be taken as:

$$S_s = \frac{C_a}{1+e_o} H_c \log \left(\frac{t_2}{t_1} \right) \quad (10.6.2.4.3-9)$$

Where laboratory test results are expressed in terms of vertical strain, ϵ_v , the secondary settlement of footings on cohesive soils shall be taken as:

$$S_s = C_{\alpha} H_c \log \left(\frac{t_2}{t_1} \right) \quad (10.6.2.4.3-10)$$

practical assumption is usually made that the additional consolidation past 90 percent or 95 percent consolidation is negligible, or is taken into consideration as part of the total long-term settlement. Refer to Winterkorn and Fang (1975) for values of T for excess pore pressure distributions other than indicated in Figure 10.6.2.4.3-4.

The length of the drainage path is the longest distance from any point in a compressible layer to a drainage boundary at the top or bottom of the compressible soil unit. Where a compressible layer is located between two drainage boundaries, H_d equals one-half the actual height of the layer. Where a compressible layer is adjacent to an impermeable boundary (usually below), H_d equals the full height of the layer.

Computations to predict the time rate of consolidation based on the result of laboratory tests generally tend to over-estimate the actual time required for consolidation in the field. This over-estimation is principally due to:

- the presence of thin drainage layers within the compressible layer that are not observed from the subsurface exploration nor considered in the settlement computations;
- the effects of three-dimensional dissipation of pore water pressures in the field, rather than the one-dimensional dissipation that is imposed by laboratory odometer tests and assumed in the computations; and
- the effects of sample disturbance, which tend to reduce the permeability of the laboratory tested samples.

If the total consolidation settlement is within the serviceability limits for the structure, the time rate of consolidation is usually of lesser concern for spread footings. If the total consolidation settlement exceeds the serviceability limitations, superstructure damage will occur unless provisions are made for timing of closure pours as a function of settlement, simple support of spans and/or periodic jacking of bearing supports.

Secondary compression component if settlement results from compression of bonds between individual clay particles and domains, as well as other effects on the microscale that are not yet clearly understood (Holtz and Kovacs, 1981). Secondary settlement is most important for highly plastic clays and organic and micaceous soils. Accordingly, secondary settlement predictions should be considered as approximate estimates only.

If secondary compression is estimated to exceed serviceability limitations, either deep foundations or ground improvement should be considered to mitigate the effects of secondary compression. Experience indicates preloading and surcharging may not be effective in eliminating secondary compression.

where:

- H_c = initial height of compressible soil layer (ft)
 e_o = void ratio at initial vertical effective stress (dim)
 t_1 = time when secondary settlement begins, i.e., typically at a time equivalent to 90 percent average degree of primary consolidation (yr)
 t_2 = arbitrary time that could represent the service life of the structure (yr)
 C_{α} = secondary compression index estimated from the results of laboratory consolidation testing of undisturbed soil samples (dim)
 $C_{\alpha s}$ = modified secondary compression index estimated from the results of laboratory consolidation testing of undisturbed soil samples (dim)

10.6.2.4.4—Settlement of Footings on Rock

For footings bearing on fair to very good rock, according to the Geomechanics Classification system and designed in accordance with the provisions of this Section, elastic settlements may generally be assumed to be less than 0.5 in. When elastic settlements of this magnitude are unacceptable or when the rock is not competent, an analysis of settlement based on rock mass characteristics shall be made.

Where rock is broken or jointed (relative rating of ten or less for RQD and joint spacing), the rock joint condition is poor (relative rating of ten or less) or the criteria for fair to very good rock are not met, a settlement analysis should be conducted, and the influence of rock type, condition of discontinuities, and degree of weathering shall be considered in the settlement analysis.

The elastic settlement of footings on broken or jointed rock, in feet, should be taken as:

- For circular (or square) footings:

$$\rho = q_o (1 - \nu^2) \frac{r I_p}{144 E_m} \quad (10.6.2.4.4-1)$$

in which:

$$I_p = \frac{(\sqrt{\pi})}{\beta_z} \quad (10.6.2.4.4-2)$$

- For rectangular footings:

$$\rho = q_o (1 - \nu^2) \frac{B I_p}{144 E_m} \quad (10.6.2.4.4-3)$$

in which:

$$I_p = \frac{(L/B)^{1/2}}{\beta_z} \quad (10.6.2.4.4-4)$$

C10.6.2.4.4

In most cases, it is sufficient to determine settlement using the average bearing stress under the footing.

Where the foundations are subjected to a very large load or where settlement tolerance may be small, settlements of footings on rock may be estimated using elastic theory. The stiffness of the rock mass should be used in such analyses.

The accuracy with which settlements can be estimated by using elastic theory is dependent on the accuracy of the estimated rock mass modulus, E_m . In some cases, the value of E_m can be estimated through empirical correlation with the value of the modulus of elasticity for the intact rock between joints. For unusual or poor rock mass conditions, it may be necessary to determine the modulus from in-situ tests, such as plate loading and pressuremeter tests.

where:

- q_o = applied vertical stress at base of loaded area (ksf)
- ν = Poisson's Ratio (dim)
- r = radius of circular footing or $B/2$ for square footing (ft)
- I_p = influence coefficient to account for rigidity and dimensions of footing (dim)
- E_m = rock mass modulus (ksi)
- β_z = factor to account for footing shape and rigidity (dim)

Values of I_p should be computed using the β_z values presented in Table 10.6.2.4.4-1 for rigid footings. Where the results of laboratory testing are not available, values of Poisson's ratio, ν , for typical rock types may be taken as specified in Table C10.4.6.5-2. Determination of the rock mass modulus, E_m , should be based on the methods described in Sabatini et al. (2002).

The magnitude of consolidation and secondary settlements in rock masses containing soft seams or other material with time-dependent settlement characteristics should be estimated by applying procedures specified in Article 10.6.2.4.3.

Table 10.6.2.4.4-1—Elastic Shape and Rigidity Factors, EPRI (1983)

L/B	Flexible, β_z (average)	β_z Rigid
Circular	1.04	1.13
1	1.06	1.08
2	1.09	1.10
3	1.13	1.15
5	1.22	1.24
10	1.41	1.41

10.6.2.5—Bearing Resistance at the Service Limit State

10.6.2.5.1—Presumptive Values for Bearing Resistance

The use of presumptive values shall be based on knowledge of geological conditions at or near the structure site.

C10.6.2.5.1

Unless more appropriate regional data are available, the presumptive values given in Table C10.6.2.5.1-1 may be used. These bearing resistances are settlement limited, e.g., 1.0 in., and apply only at the service limit state.

Table C10.6.2.5.1-1—Presumptive Bearing Resistance for Spread Footing Foundations at the Service Limit State Modified after U.S. Department of the Navy (1982)

Type of Bearing Material	Consistency in Place	Bearing Resistance (ksf)	
		Ordinary Range	Recommended Value of Use
Massive crystalline igneous and metamorphic rock: granite, diorite, basalt, gneiss, thoroughly cemented conglomerate (sound condition allows minor cracks)	Very hard, sound rock	120–200	160
Foliated metamorphic rock: slate, schist (sound condition allows minor cracks)	Hard sound rock	60–80	70
Sedimentary rock: hard cemented shales, siltstone, sandstone, limestone without cavities	Hard sound rock	30–50	40
Weathered or broken bedrock of any kind, except highly argillaceous rock (shale)	Medium hard rock	16–24	20
Compaction shale or other highly argillaceous rock in sound condition	Medium hard rock	16–24	20
Well-graded mixture of fine- and coarse-grained soil: glacial till, hardpan, boulder clay (GW-GC, GC, SC)	Very dense	16–24	20
Gravel, gravel-sand mixture, boulder-gravel mixtures (GW, GP, SW, SP)	Very dense	12–20	14
	Medium dense to dense	8–14	10
	Loose	4–12	6
Coarse to medium sand, and with little gravel (SW, SP)	Very dense	8–12	8
	Medium dense to dense	4–8	6
	Loose	2–6	3
Fine to medium sand, silty or clayey medium to coarse sand (SW, SM, SC)	Very dense	6–10	6
	Medium dense to dense	4–8	5
	Loose	2–4	3
Fine sand, silty or clayey medium to fine sand (SP, SM, SC)	Very dense	6–10	6
	Medium dense to dense	4–8	5
	Loose	2–4	3
Homogeneous inorganic clay, sandy or silty clay (CL, CH)	Very dense	6–12	8
	Medium dense to dense	2–6	4
	Loose	1–2	1
Inorganic silt, sandy or clayey silt, varved silt-clay-fine sand (ML, MH)	Very stiff to hard	4–8	6
	Medium stiff to stiff	2–6	3
	Soft	1–2	1

10.6.2.5.2—Semiempirical Procedures for Bearing Resistance

Bearing resistance on rock shall be determined using empirical correlation to the RMR. Local experience should be considered in the use of these semi-empirical procedures.

If the recommended value of presumptive bearing resistance exceeds either the unconfined compressive strength of the rock or the nominal resistance of the concrete, the presumptive bearing resistance shall be taken as the lesser of the unconfined compressive strength of the rock or the nominal resistance of the concrete. The nominal resistance of concrete shall be taken as $0.3f'_c$.

Consideration should be given to the relative change in the computed nominal resistance based on effective versus gross footing dimensions for the size of footings typically used for bridges. Judgment should be used in deciding whether the use of gross footing dimensions for computing nominal bearing resistance at the strength limit state would result in a conservative design.

10.6.3.1.2—Theoretical Estimation

10.6.3.1.2a—Basic Formulation

C10.6.3.1.2a

The nominal bearing resistance shall be estimated using accepted soil mechanics theories and should be based on measured soil parameters. The soil parameters used in the analyses shall be representative of the soil shear strength under the considered loading and subsurface conditions.

The nominal bearing resistance of spread footings on cohesionless soils shall be evaluated using effective stress analyses and drained soil strength parameters.

The nominal bearing resistance of spread footings on cohesive soils shall be evaluated for total stress analyses and undrained soil strength parameters. In cases where the cohesive soils may soften and lose strength with time, the bearing resistance of these soils shall also be evaluated for permanent loading conditions using effective stress analyses and drained soil strength parameters.

For spread footings bearing on compacted soils, the nominal bearing resistance shall be evaluated using the more critical of either total or effective stress analyses.

Except as noted below, the nominal bearing resistance of a soil layer, in ksf, should be taken as:

$$q_n = cN_{cm} + \gamma_q D_f N_{qm} C_{wq} + 0.5\gamma_f B N_{\gamma m} C_{w\gamma} \quad (10.6.3.1.2a-1)$$

in which:

$$N_{cm} = N_c s_c i_c \quad (10.6.3.1.2a-2)$$

$$N_{qm} = N_q s_q d_q i_q \quad (10.6.3.1.2a-3)$$

$$N_{\gamma m} = N_{\gamma} s_{\gamma} i_{\gamma} \quad (10.6.3.1.2a-4)$$

where:

- c = cohesion, taken as undrained shear strength (ksf)
- N_c = cohesion term (undrained loading) bearing capacity factor, as specified in Table 10.6.3.1.2a-1 (dim)
- N_q = surcharge (embedment) term (drained or undrained loading) bearing capacity factor, as specified in Table 10.6.3.1.2a-1 (dim)

The bearing resistance formulation provided in Eqs. 10.6.3.1.2a-1 through 10.6.3.1.2a-4 is the complete formulation as described in the Munfakh et al. (2001). However, in practice, not all of the factors included in these equations have been routinely used.

- N_γ = unit weight (footing width) term (drained loading) bearing capacity factor, as specified in Table 10.6.3.1.2a-1 (dim)
 γ_q = total (moist) unit weight of soil above the bearing depth of the footing (kcf)
 γ_f = total (moist) unit weight of soil below the bearing depth of the footing (kcf)
 D_f = footing embedment depth (ft)
 B = footing width (ft)
 $C_{wq}, C_{w\gamma}$ = correction factors to account for the location of the groundwater table, as specified in Table 10.6.3.1.2a-2 (dim)
 s_c, s_γ, s_q = footing shape correction factors, as specified in Table 10.6.3.1.2a-3 (dim)
 d_q = depth correction factor to account for the shearing resistance along the failure surface passing through cohesionless material above the bearing elevation determined from Eq. 10.6.3.1.2a-10 (dim)
 i_c, i_γ, i_q = load inclination factors determined from Eqs. 10.6.3.1.2a-5 or 10.6.3.1.2a-6, and 10.6.3.1.2a-7 and 10.6.3.1.2a-8 (dim)

For $\phi_f = 0$:

$$i_c = 1 - (mH/cBLN_c) \quad (10.6.3.1.2a-5)$$

For $\phi_f > 0$:

$$i_c = i_q - [(1 - i_q)/(N_q - 1)] \quad (10.6.3.1.2a-6)$$

in which:

$$i_q = \left[1 - \frac{H}{(V + cBL \cot \phi_f)} \right]^n \quad (10.6.3.1.2a-7)$$

$$i_\gamma = \left[1 - \frac{H}{V + cBL \cot \phi_f} \right]^{(n+1)} \quad (10.6.3.1.2a-8)$$

$$n = [(2 + L/B)/(1 + L/B)] \cos^2 \theta + [(2 + B/L)/(1 + B/L)] \sin^2 \theta \quad (10.6.3.1.2a-9)$$

where:

- B = footing width (ft)
 L = footing length (ft)
 H = unfactored horizontal load (kips)
 V = unfactored vertical load (kips)
 θ = projected direction of load in the plane of the footing, measured from the side of length, L (degrees)

Most geotechnical engineers nationwide have not used the load inclination factors. This is due, in part, to the lack of knowledge of the vertical and horizontal loads at the time of geotechnical explorations and preparation of bearing resistance recommendations.

Furthermore, the basis of the load inclination factors computed by Eqs. 10.6.3.1.2a-5 to 10.6.3.1.2a-8 is a combination of bearing resistance theory and small scale load tests on 1.0 in. wide plates on London Clay and Ham River Sand (Meyerhof, 1953). Therefore, the factors do not take into consideration the effects of depth of embedment. Meyerhof further showed that for footings with a depth of embedment ratio of $D_f/B = 1$, the effects of load inclination on bearing resistance are relatively small. The theoretical formulation of load inclination factors were further examined by Brinch-Hansen (1970), with additional modification by Vesic' (1973) into the form provided in Eqs. 10.6.3.1.2a-5 to 10.6.3.1.2a-8.

It should further be noted that the resistance factors provided in Article 10.5.5.2.2 were derived for vertical loads. The applicability of these resistance factors to design of footings resisting inclined load combinations is not currently known. The combination of the resistance factors and the load inclination factors may be overly conservative for footings with an embedment of approximately $D_f/B = 1$ or deeper because the load inclination factors were derived for footings without embedment.

In practice, therefore, for footings with modest embedment, consideration may be given to omission of the load inclination factors.

Figure C10.6.3.1.2a-1 shows the convention for determining the θ angle in Eq. 10.6.3.1.2a-9.

Figure C10.6.3.1.2a-1—Inclined Loading Conventions

Table 10.6.3.1.2a-2—Coefficients C_{wq} and $C_{w\gamma}$ for Various Groundwater Depths

D_w	C_{wq}	$C_{w\gamma}$
0.0	0.5	0.5
D_f	1.0	0.5
$>1.5B + D_f$	1.0	1.0

Where the position of groundwater is at a depth less than 1.5 times the footing width below the footing base, the bearing resistance is affected. The highest anticipated groundwater level should be used in design.

Table 10.6.3.1.2a-3—Shape Correction Factors s_c , s_γ , s_q

Factor	Friction Angle	Cohesion Term (s_c)	Unit Weight Term (s_γ)	Surcharge Term (s_q)
Shape Factors s_c, s_γ, s_q	$\phi_f = 0$	$1 + \left(\frac{B}{5L} \right)$	1.0	1.0
	$\phi_f > 0$	$1 + \left(\frac{B}{L} \right) \left(\frac{N_q}{N_c} \right)$	$1 - 0.4 \left(\frac{B}{L} \right)$	$1 + \left(\frac{B}{L} \tan \phi_f \right)$

$$d_q = 1 + 2 \tan \phi_f (1 - \sin \phi_f)^2 \arctan \left(\frac{D_f}{B} \right) \quad (10.6.3.1.2a-10)$$

Eq. 10.6.3.1.2a-10 has been verified to cover a range of friction angle, ϕ_f , of 32 degrees to 42 degrees, and a range of D_f/B of 1 to 8. Depth correction factor values beyond this range have not been verified at this time.

where:

d_q = depth correction factor to account for the shearing resistance along the failure surface passing through cohesionless material above the bearing elevation(dim)

ϕ_f = angle of internal friction of soil (degrees)

D_f = footing embedment depth (ft)

B = footing width (ft)

$\text{Arctan}(D_f/B)$ is in radians.

The depth correction factor should be used only when the soils above the footing bearing elevation are as competent as the soils beneath the footing level; otherwise, the depth correction factor should be taken as 1.0. The depth correction factor, d_q , shall not exceed 1.4.

10.6.3.1.2b—Considerations for Punching Shear

C10.6.3.1.2b

If local or punching shear failure is possible, the nominal bearing resistance shall be estimated using reduced shear strength parameters c^* and ϕ^* in Eqs. 10.6.3.1.2b-1 and 10.6.3.1.2b-2. The reduced shear parameters may be taken as:

$$c^* = 0.67c \quad (10.6.3.1.2b-1)$$

$$\phi^* = \tan^{-1}(0.67 \tan \phi_f) \quad (10.6.3.1.2b-2)$$

where:

c^* = reduced effective stress soil cohesion for punching shear (ksf)

ϕ^* = reduced effective stress soil friction angle for punching shear (degrees)

Local shear failure is characterized by a failure surface that is similar to that of a general shear failure but that does not extend to the ground surface, ending somewhere in the soil below the footing. Local shear failure is accompanied by vertical compression of soil below the footing and visible bulging of soil adjacent to the footing but not by sudden rotation or tilting of the footing. Local shear failure is a transitional condition between general and punching shear failure. Punching shear failure is characterized by vertical shear around the perimeter of the footing and is accompanied by a vertical movement of the footing and compression of the soil immediately below the footing but does not affect the soil outside the loaded area. Punching shear failure occurs in loose or compressible soils, in weak soils under slow (drained) loading, and in dense sands for deep footings subjected to high loads.

Figure C10.6.3.1.2b-1—Modes of Bearing Capacity Failure for Footings in Sand

10.6.3.1.2c—Considerations for Footings on Slopes

For footings constructed on or adjacent to slopes, the nominal bearing resistance shall be determined using a reduction coefficient (RC_{BC}) as presented in Tables 10.6.3.1.2c-1 and 10.6.3.1.2c-2. The reduction coefficient should be applied directly to the nominal bearing resistance calculated from Eq. 10.6.3.1.2a-1 for footings on level ground and supported on the same foundation soil conditions.

The nominal resistance of footings on or adjacent to slopes shall be taken as:

$$q_{n-sloping\ ground} = RC_{BC} q_n = RC_{BC} (cN_c + 0.5\gamma BN_\gamma) \quad (10.6.3.1.2c-1)$$

where:

$q_{n-sloping\ ground}$ = the nominal footing bearing resistance considering the effect of sloping ground (ksf)

RC_{BC} = reduction coefficient for bearing resistance due to slope effects (dim)

and other variables are as defined in Article 10.6.3.1.2a and Figure 10.6.3.1.2c-1. The bearing capacity factors N_c and N_γ are obtained in accordance with Article 10.6.3.1.2a.

Reduction coefficients (RC_{BC}) should be determined using the definitions illustrated in Figure 10.6.3.1.2c-1

C10.6.3.1.2c

A rational approach for determining a modified bearing resistance for footings on or adjacent to a slope is presented in Leshchinsky (2015) and Leshchinsky and Xie (2016). These methods are considered valid and applicable to structure foundations in addition to the MSE retaining wall example presented in the reference papers. The reduction coefficients provided in Tables 10.6.3.1.2c-1 and 10.6.3.1.2c-2 are modified and reconfigured by the author of the cited papers to allow for more convenient use in practice. See the original papers for the complete tabulation of reduction coefficient values.

The reduction coefficients are applicable to purely cohesive, purely cohesionless and $c-\phi$ soils. The RC_{BC} factors are based on no footing embedment for footings either on or adjacent to slopes and may be conservative for deep footing embedment depths.

Limit analysis, or limit equilibrium analysis, should be considered to estimate the nominal bearing resistance of footings on or adjacent to slopes composed of soils and/or site conditions that are not consistent with the parameters and conditions described in the reference documents (i.e. embedment >0, layered soils, steeper slopes).

The schematic shown in Figure 10.6.3.1.2c-1 is provided only for illustrating and defining the terms used in the design equations and tables. This figure should not be used as the basis for locating footings on slopes regarding embedment depth and setback.

for footings on or adjacent to slopes. Use linear interpolation to obtain reduction coefficients for values not provided. The slope stability factor, N_s , in Tables 10.6.3.1.2c-1 and 10.6.3.1.2c-2 shall be taken as:

$$N_s = \frac{\gamma H_s}{c} \quad (10.6.3.1.2c-2)$$

where:

N_s = slope stability factor (dim)

H_s = height of sloping ground surface below bottom of footing (ft)

and other variables are as defined in Article 10.6.3.1.2a.

Figure 10.6.3.1.2c-1—Definition of Footing and Slope Geometric Parameters for Determination of RC_{BC}

Table 10.6.3.1.2c-1—Reduction Coefficients (RC_{BC}) for Footings Placed on Slopes Composed of either Purely Cohesive Soils, ($\phi = 0$); Purely Cohesionless Soils ($c'=0$); or Soils with both Cohesive and Cohesionless Strength Components

10.6.3.1.2d—Considerations for Two-Layer Soil Systems—Critical Depth

Where the soil profile contains a second layer of soil with different properties affecting shear strength within a distance below the footing less than H_{crit} , the bearing resistance of the layered soil profile shall be determined using the provisions for two-layered soil systems herein. The distance H_{crit} , in feet, may be taken as:

$$H_{crit} = \frac{(3B) \ln \left(\frac{q_1}{q_2} \right)}{2 \left(1 + \frac{B}{L} \right)} \quad (10.6.3.1.2d-1)$$

where:

- q_1 = nominal bearing resistance of footing supported in the upper layer of a two-layer system, assuming the upper layer is infinitely thick (ksf)
- q_2 = nominal bearing resistance of a fictitious footing of the same size and shape as the actual footing but supported on surface of the second (lower) layer of a two-layer system (ksf)
- B = footing width (ft)
- L = footing length (ft)

10.6.3.1.2e—Two-Layered Soil System in Undrained Loading

C10.6.3.1.2e

Where a footing is supported on a two-layered soil system subjected to undrained loading, the nominal bearing resistance may be determined using Eq. 10.6.3.1.2a-1 with the following modifications:

- c_1 = undrained shear strength of the top layer of soil as depicted in Figure 10.6.3.1.2e-1 (ksf)
- N_{cm} = N_m , a bearing capacity factor, as specified below (dim)
- N_{qm} = 1.0 (dim)

Where the bearing stratum overlies a stiffer cohesive soil, N_m , may be taken as specified in Figure 10.6.3.1.2e-2.

Where the bearing stratum overlies a softer cohesive soil, N_m may be taken as:

$$N_m = \left(\frac{1}{\beta_m} + \kappa s_c N_c \right) \leq s_c N_c \quad (10.6.3.1.2e-1)$$

in which:

$$\beta_m = \frac{BL}{2(B+L)H_{s2}} \quad (10.6.3.1.2e-2)$$

Vesic' (1970) developed a rigorous solution for the modified bearing capacity factor, N_m , for the weak undrained layer over strong undrained layer situation. This solution is given by the following equation:

$$N_m = \frac{\kappa N_c^* (N_c^* + \beta_m - 1) A}{[B \times C] - [(\kappa N_c^* + \beta_m - 1)(N_c^* + 1)]} \quad (C10.6.3.1.2e-1)$$

in which:

$$A = [(\kappa + 1)N_c^{*2} + (1 + \kappa\beta_m)N_c^* + \beta_m - 1] \quad (C10.6.3.1.2e-2)$$

$$B = [\kappa(\kappa + 1)N_c^* + \kappa + \beta_m - 1] \quad (C10.6.3.1.2e-3)$$

$$C = [(N_c^* + \beta_m)N_c^* + \beta_m - 1] \quad (C10.6.3.1.2e-4)$$

- For circular or square footings:

$$\beta_m = \frac{B}{4H_{s2}} \quad (C10.6.3.1.2e-5)$$

$$N_c^* = 6.17$$

$$\kappa = \frac{c_2}{c_1} \quad (10.6.3.1.2e-3)$$

where:

- β_m = punching index (dim)
- c_1 = undrained shear strength of upper soil layer (ksf)
- c_2 = undrained shear strength of lower soil layer (ksf)
- H_{s2} = distance from bottom of footing to top of the second soil layer (ft)
- s_c = shape correction factor determined from Table 10.6.3.1.2a-3
- N_c = bearing capacity factor determined herein (dim)
- N_{qm} = bearing capacity factor determined herein (dim)

- For strip footings:

$$\beta_m = \frac{B}{2H_{s2}} \quad (C10.6.3.1.2e-6)$$

$$N_c^* = 5.14$$

(a)

(b)

Figure 10.6.3.1.2e-1—Two-Layer Soil Profiles

Figure 10.6.3.1.2e-2—Modified Bearing Factor for Two-Layer Cohesive Soil with Weaker Soil Overlying Stronger Soil (EPRI, 1983)

10.6.3.1.2f—Two-Layered Soil System in Drained Loading

Where a footing supported on a two-layered soil system is subjected to a drained loading, the nominal bearing resistance, in ksf, may be taken as:

$$q_n = \left[q_2 + \left(\frac{1}{K} \right) c'_1 \cot \phi'_1 \right] e^{2 \left[1 + \left(\frac{B}{L} \right) K \tan \phi'_1 \left(\frac{H_2}{B} \right) \right]} - \left(\frac{1}{K} \right) c'_1 \cot \phi'_1 \quad (10.6.3.1.2f-1)$$

in which:

$$K = \frac{1 - \sin^2 \phi'_1}{1 + \sin^2 \phi'_1} \quad (10.6.3.1.2f-2)$$

where:

- c'_1 = drained shear strength of the top layer of soil in a two-layer system, such as depicted in Figure 10.6.3.1.2e-1 (ksf)
- q_2 = nominal bearing resistance of a fictitious footing of the same size and shape as the actual footing but supported on surface of the second (lower) layer of a two-layer system (ksf)
- ϕ'_1 = effective stress angle of internal friction of the top layer of soil (degrees)

10.6.3.1.3—Semiempirical Procedures

The nominal bearing resistance of foundation soils may be estimated from the results of in-situ tests or by observed resistance of similar soils. The use of a particular in-situ test and the interpretation of test results should take local experience into consideration. The following in-situ tests may be used:

C10.6.3.1.2f

If the upper layer is a cohesionless soil and ϕ' equals 25–50 degrees, Eq. 10.6.3.1.2f-1 reduces to:

$$q_n = q_2 e^{0.67 \left[1 + \left(\frac{B}{L} \right) \right] \frac{H_2}{B}} \quad (C10.6.3.1.2f-1)$$

C10.6.3.1.3

In application of these empirical methods, the use of average SPT blow counts and CPT tip resistances is specified. The resistance factors recommended for bearing resistance included in Table 10.5.5.2.2-1 assume the use of average values for these parameters. The use of lower bound values may result in an overly conservative design. However, depending on the availability of soil

- SPT
- CPT

The nominal bearing resistance in sand, in ksf, based on SPT results may be taken as:

$$q_n = \frac{\bar{N}l_{60}B}{5} \left(C_{wq} \frac{D_f}{B} + C_{w\gamma} \right) \quad (10.6.3.1.3-1)$$

where:

$\bar{N}_{1_{60}}$ = average SPT blow count corrected for both overburden and hammer efficiency effects (blows/ft), as specified in Article 10.4.6.2.4. Average the blow count over a depth range from the bottom of the footing to $1.5B$ below the bottom of the footing.

$$B = \text{footing width (ft)}$$

C_{wg} , $C_{w\gamma}$ = correction factors to account for the location of the groundwater table, as specified in Table 10.6.3.1.2a-2 (dim)

D_f = footing embedment depth taken to the bottom of the footing (ft)

The nominal bearing resistance, in ksf, for footings on cohesionless soils based on CPT results may be taken as:

$$q_n = \frac{\bar{q}_c B}{40} \left(C_{wq} \frac{D_f}{B} + C_{w\gamma} \right) \quad (10.6.3.1.3-2)$$

where:

$\bar{q}_c$ = average cone tip resistance within a depth range, B , below the bottom of the footing (ksf)

$$B = \text{footing width (ft)}$$

C_{wy}, C_{wz} = correction factors to account for the location of the groundwater table, as specified in Table 10.6.3.1.2a-2 (dim)

D_f = footing embedment depth taken to the bottom of the footing (ft)

10.6.3.1.4—Plate Load Tests

The nominal bearing resistance may be determined by plate load tests, provided that adequate subsurface explorations have been made to determine the soil profile below the foundation. Where plate load tests are conducted, they should be conducted in accordance with ASTM D1196/D1196M.

The nominal bearing resistance determined from a plate load test may be extrapolated to adjacent footings where the subsurface profile is confirmed by subsurface exploration to be similar.

property data and the variability of the geologic strata under consideration, it may not be possible to reliably estimate the average value of the properties needed for design. In such cases, the Engineer may have no choice but to use a more conservative selection of design input parameters to mitigate the additional risks created by potential variability or the paucity of relevant data.

The original derivation of Eqs. 10.6.3.1.3-1 and 10.6.3.1.3-2 did not include inclination factors (Meverhof, 1956).

C10.6.3.1.4

Plate load tests have a limited depth of influence and furthermore may not disclose the potential for long-term consolidation of foundation soils.

Scale effects should be addressed when extrapolating the results to performance of full scale footings. Extrapolation of the plate load test data to a full scale footing should be based on the design procedures provided herein for settlement (service limit state) and bearing resistance (strength and extreme event limit state), with consideration to the effect of the stratification, e.g., layer thicknesses, depths, and properties. Plate load test results should be applied only within a sub-area of the

project site for which the subsurface conditions, e.g., stratification, geologic history, and properties, are relatively uniform.

10.6.3.2—Bearing Resistance of Rock

10.6.3.2.1—General

The methods used for design of footings on rock shall consider the presence, orientation, and condition of discontinuities, weathering profiles, and other similar profiles as they apply at a particular site.

For footings on competent rock, reliance on simple and direct analyses based on uniaxial compressive rock strengths and RQD may be applicable. For footings on less competent rock, more detailed investigations and analyses shall be performed to account for the effects of weathering and the presence and condition of discontinuities.

The designer shall judge the competency of a rock mass by taking into consideration both the nature of the intact rock and the orientation and condition of discontinuities of the overall rock mass. Where engineering judgment does not verify the presence of competent rock, the competency of the rock mass should be verified using the procedures for RMR rating.

10.6.3.2.2—Semiempirical Procedures

The nominal bearing resistance of rock should be determined using empirical correlation with the Geomechanics RMR system. Local experience shall be considered in the use of these semi-empirical procedures.

The factored bearing stress of the foundation shall not be taken to be greater than the factored compressive resistance of the footing concrete.

10.6.3.2.3—Analytic Method

The nominal bearing resistance of foundations on rock shall be determined using established rock mechanics principles based on the rock mass strength parameters. The influence of discontinuities on the failure mode shall also be considered.

10.6.3.2.4—Load Test

Where appropriate, load tests may be performed to determine the nominal bearing resistance of foundations on rock.

C10.6.3.2.1

The design of spread footings bearing on rock is frequently controlled by either overall stability, e.g., the orientation and conditions of discontinuities, or load eccentricity considerations. The designer should verify adequate overall stability and size the footing based on eccentricity requirements at the strength limit state before checking nominal bearing resistance at both the service and strength limit states.

The design procedures for foundations in rock have been developed using the RMR, rock mass rating system. Classification of the rock mass should be according to the RMR system. For additional information on the RMR system, see Sabatini et al. (2002).

C10.6.3.2.2

The bearing resistance of jointed or broken rock may be estimated using the semi-empirical procedure developed by Carter and Kulhawy (1988). This procedure is based on the unconfined compressive strength of the intact rock core sample. Depending on rock mass quality measured in terms of RMR system, the nominal bearing resistance of a rock mass varies from a small fraction to six times the unconfined compressive strength of intact rock core samples.

C10.6.3.2.3

Depending upon the relative spacing of joints and rock layering, bearing capacity failures for foundations on rock may take several forms. Except for the case of a rock mass with closed joints, the failure modes are different from those in soil. Procedures for estimating bearing resistance for each of the failure modes can be found in Kulhawy and Goodman (1987), Goodman (1989), and Sowers (1979).

10.6.3.3—Eccentric Load Limitations

The eccentricity of loading at the strength limit state, evaluated based on factored loads shall not exceed:

- One-third of the corresponding footing dimension, B or L , for footings on soils, or 0.45 of the corresponding footing dimensions B or L , for footings on rock.

10.6.3.4—Failure by Sliding

Failure by sliding shall be investigated for footings that support horizontal or inclined load and/or are founded on slopes.

For foundations on clay soils, the possible presence of a shrinkage gap between the soil and the foundation shall be considered. If passive resistance is included as part of the shear resistance required for resisting sliding, consideration shall also be given to possible future removal of the soil in front of the foundation.

The factored resistance against failure by sliding, in kips, shall be taken as:

$$R_R = \phi R_n = \phi_\tau R_\tau + \phi_{ep} R_{ep} \quad (10.6.3.4-1)$$

where:

- ϕ = resistance factor (dim)
- R_n = nominal sliding resistance against failure by sliding (kips)
- ϕ_τ = resistance factor for shear resistance between soil and foundation, specified in Table 10.5.5.2.2-1
- R_τ = nominal sliding resistance between soil and foundation (kips)
- ϕ_{ep} = resistance factor for passive resistance, specified in Table 10.5.5.2.2-1
- R_{ep} = nominal passive resistance of soil available throughout the design life of the structure (kips)

If the soil beneath the footing is cohesionless, the nominal sliding resistance between soil and foundation shall be taken as:

$$R_\tau = CV \tan \phi_f \quad (10.6.3.4-2)$$

for which:

- C = 1.0 for concrete cast against soil
- = 0.8 for precast concrete footing

where:

C10.6.3.3

A comprehensive parametric study was conducted for cantilevered retaining walls of various heights and soil conditions. The base widths obtained using the LRFD load factors and eccentricity of $B/3$ were comparable to those of ASD with an eccentricity of $B/6$. For foundations on rock, to obtain equivalence with ASD specifications, a maximum eccentricity of $B/2$ would be needed for LRFD. However, a slightly smaller maximum eccentricity has been specified to account for the potential unknown future loading that could push the resultant outside the footing dimensions.

C10.6.3.4

Sliding failure occurs if the force effects due to the horizontal component of loads exceed the more critical of either the factored shear resistance of the soils or the factored shear resistance at the interface between the soil and the foundation.

For footings on cohesionless soils, sliding resistance depends on the roughness of the interface between the foundation and the soil.

The magnitudes of active earth load and passive resistance depend on the type of backfill material, the wall movement, and the compactive effort. Their magnitude can be estimated using procedures described in Sections 3 and 11.

In most cases, the movement of the structure and its foundation will be small. Consequently, if passive resistance is included in the resistance, its magnitude is commonly taken as 50 percent of the maximum passive resistance. This is the basis for the resistance factor, ϕ_{ep} , in Table 10.5.5.2.2-1.

The units for R_R , R_n , and R_{ep} are shown in kips. For elements designed on a unit length basis, these quantities will have the units of kips per unit length.

Sliding resistance between the base of a shallow foundation and a granular soil is governed by the coefficient of friction ($\tan \delta$) between the foundation soil and the footing. The value of the coefficient of friction is a function of the soil type and the roughness of the footing. For concrete cast against cohesionless or granular material, the footing base is rough, and the coefficient of friction, $\tan \delta$, will be equal to the tangent of the friction angle ($\tan \phi_f$) for the soil supporting the footing. If the bottom of the footing consists of something other than concrete cast against the ground, then the coefficient of friction ($\tan \delta$) is not solely a property of the soil but is also a function of the footing material type and the roughness of the footing material. For the case of a precast

ϕ_f	= internal friction angle of drained soil (degrees)
V	= total vertical force (kips)

concrete footing, assuming the concrete is smooth, the coefficient of friction should be set equal to 80 percent of $\tan \phi$. See Article C3.11.5.3 for additional guidance and background on the determination of interface friction values.

In the absence of specific data (e.g., measured ϕ_f from laboratory testing, ϕ_f determined through correlation to in-situ measured SPT or cone resistance values, or measured $\tan \delta$ from laboratory testing), experience has shown that Table C3.11.5.3-1 may be used to estimate the coefficient of friction $\tan \delta$ between soil and various footing material types in Eq. 10.6.3.4-2.

For footings that rest on clay, where footings are supported on at least 6.0 in. of compacted granular material, the sliding resistance may be taken as the lesser of:

- the cohesion of the clay, or
- one-half the normal stress on the interface between the footing and soil, as shown in Figure 10.6.3.4-1 for retaining walls.

The following notation shall be taken to apply to Figure 10.6.3.4-1:

q_s = unit shear resistance, equal to S_u or $0.5 \sigma'_v$, whichever is less (ksf)
 R_z = nominal sliding resistance between soil and foundation (kips) expressed as the shaded area under the q_s diagram
 S_u = undrained shear strength (ksf)
 σ'_v = vertical effective stress (ksf)

Figure 10.6.3.4-1—Procedure for Estimating Nominal Sliding Resistance for Walls on Clay

10.6.3.5—Overall Stability

Overall stability of a footing shall be evaluated where one or more of the following conditions exist:

- Horizontal or inclined loads are present,
- The foundation is placed on embankment,
- The footing is located on, near or within a slope,
- The possibility of loss of foundation support through erosion or scour exists, or
- Bearing strata are significantly inclined.

10.6.4—Extreme Event Limit State Design

10.6.4.1—General

Extreme limit state design checks for spread footings shall include, but not necessarily be limited to:

- bearing resistance,
- eccentric load limitations (overturning),
- sliding, and
- overall stability.

Resistance factors shall be as specified in Article 10.5.5.3.

10.6.4.2—Eccentric Load Limitations

For footings, whether on soil or on rock, the eccentricity of loading for extreme limit states shall not exceed the limits provided in Article 11.6.5.

If live loads act to reduce the eccentricity for the Extreme I limit state, γ_{EQ} shall be taken as 0.0.

10.6.5—Structural Design

The structural design of footings shall comply with the requirements given in Section 5.

For structural design of an eccentrically loaded foundation, a triangular or trapezoidal contact stress distribution based on factored loads shall be used for footings bearing on all soil and rock conditions.

C10.6.5

For purposes of structural design, it is usually assumed that the bearing stress varies linearly across the bottom of the footing. This assumption results in the slightly conservative triangular or trapezoidal contact stress distribution.

10.7—DRIVEN PILES

10.7.1—General

10.7.1.1—Application

Driven piling should be considered in the following situations:

- When spread footings cannot be founded on rock, or on competent soils at a reasonable cost;
- At locations where soil conditions would normally permit the use of spread footings but the potential exists for scour, liquefaction or lateral spreading,

in which case driven piles bearing on suitable materials below susceptible soils should be considered for use as a protection against these problems;

- Where right-of-way or other space limitations would not allow the use spread footings;
- Where existing soil, contaminated by hazardous materials, must be removed for the construction of spread footings; or
- Where an unacceptable amount of settlement of spread footings may occur.

10.7.1.2—Minimum Pile Spacing, Clearance, and Embedment into Cap

Center-to-center pile spacing should not be less than 30.0 in. or 2.5 pile diameters. The distance from the side of any pile to the nearest edge of the pile cap shall not be less than 9.0 in.

The tops of piles shall project at least 12.0 in. into the pile cap after all damaged material has been removed. If the pile is attached to the cap by embedded bars or strands, the pile shall extend no less than 6.0 in. into the cap.

Where a reinforced concrete beam is cast-in-place and used as a bent cap supported by piles, the concrete cover on the sides of the piles shall not be less than 6.0 in., plus an allowance for permissible pile misalignment. Where pile reinforcement is anchored in the cap satisfying the requirements of Article 5.12.9.1, the projection may be less than 6.0 in.

10.7.1.3—Piles through Embankment Fill

Piles to be driven through embankments should penetrate a minimum of 10.0 ft through original ground unless refusal on bedrock or competent bearing strata occurs at a lesser penetration.

Fill used for embankment construction should be a select material, which does not obstruct pile penetration to the required depth.

10.7.1.4—Batter Piles

When the lateral resistance of the soil surrounding the piles is inadequate to counteract the horizontal forces transmitted to the foundation, or when increased rigidity of

C10.7.1.3

If refusal occurs at a depth of less than 10 ft, other foundation types, e.g., footings or shafts, may be more effective.

To minimize the potential for obstruction of the piles, the maximum size of any rock particles in the fill should not exceed 6.0 in. Pre-drilling or spudding pile locations should be considered in situations where obstructions in the embankment fill cannot be avoided, particularly for displacement piles. Note that predrilling or spudding may reduce the pile side resistance and lateral resistance, depending on how the predrilling or spudding is conducted. The diameter of the predrilled or spudded hole, and the potential for caving of the hole before the pile is installed will need to be considered to assess the effect this will have on side and lateral resistance.

If compressible soils are located beneath the embankment, piles should be driven after embankment settlement is complete, if possible, to minimize or eliminate downdrag forces.

C10.7.1.4

In some cases, it may be desirable to use batter piles. From a general viewpoint, batter piles provide a much stiffer resistance to lateral loads than would be possible

the entire structure is required, batter piles should be considered for use. Where negative side resistance (downdrag) loads are expected, batter piles should be avoided. If batter piles are used in areas of significant seismic loading, the design of the pile foundation shall recognize the increased foundation stiffness that results.

10.7.1.5—Pile Design Requirements

Pile design shall address the following issues as appropriate:

- Nominal bearing resistance to be specified in the contract, type of pile, and size of pile group required to provide adequate support, with consideration of how nominal bearing pile resistance will be determined in the field.
- Group interaction.
- Pile quantity estimation and estimated pile penetration required to meet nominal axial resistance and other design requirements.
- Minimum pile penetration necessary to satisfy the requirements caused by uplift, scour, downdrag, settlement, liquefaction, lateral loads, and seismic conditions.
- Foundation deflection to meet the established movement and associated structure performance criteria.
- Pile foundation nominal structural resistance.
- Pile drivability to confirm that acceptable driving stresses and blow counts can be achieved at the nominal bearing resistance, and at the estimated resistance to reach the minimum tip elevation, if a minimum tip elevation is required, with an available driving system.
- Long-term durability of the pile in service, i.e., corrosion and deterioration.

10.7.1.6—Determination of Pile Loads

10.7.1.6.1—General

The loads and load factors to be used in pile foundation design shall be as specified in Section 3. Computational assumptions that shall be used in determining individual pile loads are described in Section 4.

10.7.1.6.2—Drag Load

The provisions of Article 3.11.8 shall apply for determination of drag load. For the geotechnical strength limit state, $DR = 0$. For the structural strength limit state, drag load shall be evaluated as specified in Table 3.4.1-1 using an appropriate resistance factor as specified in Article 10.5.5. Downdrag shall be considered at the service limit state using the neutral plane method.

with vertical piles. They can be very effective in resisting static lateral loads.

Due to increased foundation stiffness, batter piles may not be desirable in resisting lateral dynamic loads if the structure is located in an area where seismic loads are potentially high.

C10.7.1.5

The driven pile design process is discussed in detail in Hannigan et al. (2016).

C10.7.1.6.1

The specification and determination of top of cap loads is discussed in Section 3. The Engineer should select different levels of analysis, detail and accuracy as appropriate for the structure under consideration. Details are discussed in Section 4.

C10.7.1.6.2

Downdrag occurs when settlement of soils along the side of the piles results in downward movement of the soil relative to the pile. See Article C3.11.8.

Drag load occurs when settlement of soils along the side of piles results in axial (elastic and inelastic) compression of the pile. See Article C3.11.8. Loading at the service limit state may be significant and govern the geotechnical pile design.

At service conditions, drag load is largest when the pile toe is fixed and there is a minimum of pile structural

The nominal geotechnical pile resistance available to support structure loads plus drag load shall be estimated by all soil layers using the procedures for the neutral plane method described by Hannigan et al. (2016). This applies to limit states other than the geotechnical strength limit state.

10.7.1.6.3—Uplift Due to Expansive Soils

Piles penetrating expansive soil shall extend to a depth into moisture-stable soils sufficient to provide adequate anchorage to resist uplift. Sufficient clearance should be provided between the ground surface and underside of caps or beams connecting piles to preclude the application of uplift loads at the pile/cap connection due to swelling ground conditions.

10.7.1.6.4—Nearby Structures

Where pile foundations are placed adjacent to existing structures, the influence of the existing structure on the behavior of the foundation, and the effect of the new foundation on the existing structures, including vibration effects due to pile installation, shall be investigated.

10.7.2—Service Limit State Design

10.7.2.1—General

Service limit state design of driven pile foundations includes the evaluation of settlement due to static loads,

(top) load. There is no drag load at the geotechnical strength limit state.

The static analysis procedures in Article 10.7.3.8.6 may be used to estimate the available pile nominal resistance to withstand the drag load plus structure loads at the service limit state. Nominal resistance may also be estimated using a dynamic method, e.g., dynamic measurements with signal matching analysis, wave equation, pile driving formula, etc., per Article 10.7.3.8.

The side resistance within the zone contributing to drag load may be estimated using the static analysis methods specified in Article 10.7.3.8.6, from signal matching analysis, or from instrumented pile load test results (where strain measurements are obtained at intervals along the pile length).

Static analysis methods may have bias that, on average, over or under predicts the side resistance. The bias of the method selected to estimate the side resistance should be considered as described in Article C10.7.3.3.

C10.7.1.6.3

Evaluation of potential uplift loads on piles extending through expansive soils requires evaluation of the swell potential of the soil and the extent of the soil strata that may affect the pile. One reasonably reliable method for identifying swell potential is presented in Table 10.4.6.3-1. Alternatively, ASTM D4829 may be used to evaluate swell potential. The thickness of the potentially expansive stratum must be identified by:

- examination of soil samples from borings for the presence of jointing, slickensiding, or a blocky structure and for changes in color, and
- laboratory testing for determination of soil moisture content profiles.

C10.7.1.6.4

Vibration due to pile driving can cause settlement of existing foundations as well as structural damage to the adjacent facility, especially in loose cohesionless soils. The combination of taking measures to mitigate the vibration levels through use of nondisplacement piles, predrilling, proper hammer choice, etc., and a good vibration monitoring program should be considered.

C10.7.2.1

Lateral analysis of pile foundations is conducted to establish the load distribution between the superstructure

and drag loads if present, lateral squeeze, and lateral deformation.

The deformation caused by unbalanced lateral loads such as due to overall stability or lateral squeeze should be evaluated and addressed in the design of the pile foundation.

10.7.2.2—Tolerable Movements

The provisions of Article 10.5.2.1 shall apply.

10.7.2.3—Settlement

10.7.2.3.1—Equivalent Footing Analogy

For purposes of calculating the settlements of pile groups, loads should be assumed to act on an equivalent footing based on the depth of embedment of the piles into the layer that provides support as shown in Figures 10.7.2.3.1-1 and 10.7.2.3.1-2. The depth of the neutral plane shall be determined, and an equivalent footing should be placed at or below that depth.

Pile group settlement shall be evaluated for pile foundations in cohesive soils, soils that include cohesive layers, and piles in loose granular soils. The load used in calculating settlement shall be the nominal dead load on the foundation.

In applying the equivalent footing analogy for pile foundations, the reduction to equivalent dimensions B' and L' as used for spread footing design does not apply.

and foundations for all limit states, and to estimate the deformation in the foundation that will occur due to those loads. This Article only addresses the evaluation of the lateral deformation of the foundation resulting from the distributed loads.

C10.7.2.2

See Article C10.5.2.1.

C10.7.2.3.1

Pile design should ensure that strength limit state considerations are satisfied before checking service limit state considerations.

The neutral plane occurs at the depth where the nominal permanent load plus drag load equals the nominal side resistance plus tip resistance. The design should aim to locate the neutral plane in competent soils. Below the neutral plane, the settlement of the soil is less than the settlement of the pile and load is transferred from the pile to the soil.

Because the piles below the neutral plane will act as reinforcing elements and the compression of the pile-reinforced soil is small, pile group settlements may be calculated based on locating the neutral plane at the pile toe (Goudreault and Fellenius, 1994).

Methods for calculating settlement are discussed in Hannigan et al. (2016).

Figure 10.7.2.3.1-2—Location of Equivalent Footing (after Duncan and Buchignani, 1976)

10.7.2.3.2—Pile Groups in Cohesive Soil

C10.7.2.3.2

Shallow foundation settlement estimation procedures shall be used to estimate the settlement of a pile group, using the equivalent footing location specified in Figure 10.7.2.3.1-1 or Figure 10.7.2.3.1-2.

The settlement of pile groups in cohesionless soils may be taken as:

$$\text{Using SPT: } \rho = \frac{qI\sqrt{B}}{N_{60}} \quad (10.7.2.3.2-1)$$

$$\text{Using CPT: } \rho = \frac{qBI}{2q_c} \quad (10.7.2.3.2-2)$$

in which:

$$I = 1 - 0.125 \frac{D'}{B} \geq 0.5 \quad (10.7.2.3.2-3)$$

where:

- ρ = settlement of pile group (in.)
- q = net foundation pressure applied at $2D_b/3$, as shown in Figure 10.7.2.3.1-1; this pressure is equal to the applied load at the top of the group divided by the area of the equivalent footing and does not include the weight of the piles or the soil between the piles (ksf)
- B = width or smallest dimension of pile group (ft)

The provisions are based upon the use of empirical correlations proposed by Meyerhof (1976). These are empirical correlations and the units of measure must match those specified for correct computations. This method may tend to over-predict settlements.

I	= influence factor of the effective group embedment (dim)
D'	= effective depth, taken as $2D_b/3$ (ft)
D_b	= depth of penetration into bearing strata (ft)
N_{160}	= SPT blow count corrected for both overburden and hammer efficiency effects (blows/ft), as specified in Article 10.4.6.2.4.
q_c	= static cone tip resistance (ksf)

Alternatively, other methods for computing settlement in cohesionless soil, such as the Hough method as specified in Article 10.6.2.4.2 may also be used in connection with the equivalent footing approach.

The corrected SPT blow count or the static cone tip resistance should be averaged over a depth equal to the pile group width, B , below the equivalent footing. The SPT and CPT methods (Eqs. 10.7.2.3.2-1 and 10.7.2.3.2-2) shall only be considered applicable to the distributions shown in Figure 10.7.2.3.1-1b and Figure 10.7.2.3.1-2.

10.7.2.4—Horizontal Pile Foundation Movement

Horizontal movement induced by lateral loads shall be evaluated. The provisions of Article 10.5.2.1 shall apply regarding horizontal movement criteria.

The horizontal movement of pile foundations shall be estimated using procedures that consider soil-structure interaction. Tolerable horizontal movements of piles shall be established on the basis of confirming compatible movements of structural components, e.g., pile to column connections, for the loading condition under consideration.

The effects of the lateral resistance provided by an embedded cap may be considered in the evaluation of horizontal movement.

The orientation of nonsymmetrical pile cross-sections shall be considered when computing the pile lateral stiffness.

Lateral resistance of single piles may be determined by static load test. If a static lateral load test is to be performed, it shall follow the procedures specified in ASTM D3966.

The effects of group interaction shall be taken into account when evaluating pile group horizontal movement. When the p - y method of analysis is used, the values of p shall be multiplied by p -multiplier values, P_m , to account for group effects. The values of P_m provided in Table 10.7.2.4-1 should be used.

C10.7.2.4

Pile foundations are subjected to lateral loads due to wind, traffic loads, bridge curvature, vessel or traffic impact and earthquake. Batter piles are sometimes used but they are somewhat more expensive than vertical piles, and vertical piles are more effective against dynamic loads.

Methods of analysis that use manual computation were developed by Broms (1964a and 1964b). They are discussed in detail by Hannigan et al. (2006). Reese developed analysis methods that model the horizontal soil resistance using p - y curves. This analysis has been well developed and software is available for analyzing single piles and pile groups (Reese, 1986) (Williams et al., 2003) (Hannigan et al., 2006).

Deep foundation horizontal movement at the foundation design stage may be analyzed using computer applications that consider soil-structure interaction. Application formulations are available that consider the total structure including pile cap, pier and superstructure (Williams et al., 2003).

If a lateral static load test is used to assess the site specific lateral resistance of a pile, information on the methods of analysis and interpretation of lateral load tests presented in Reese (1984) and Kyfor et al. (1992) should be used.

Table 10.7.2.4-1—Pile p -Multipliers, P_m , for Multiple Row Shading (averaged from Hannigan et al., 2006)

Pile CTC spacing (in the direction of loading)	p -Multipliers, P_m		
	Row 1	Row 2	Row 3 and higher
$3B$	0.8	0.4	0.3
$5B$	1.0	0.85	0.7

Loading direction and spacing shall be taken as defined in Figure 10.7.2.4-1. If the loading direction for a single row of piles is perpendicular to the row (bottom detail in the Figure), a group reduction factor of less than 1.0 should only be used if the pile spacing is $5B$ or less, i.e., a P_m of 0.8 for a spacing of $3B$, as shown in Figure 10.7.2.4-1.

Figure 10.7.2.4-1—Definition of Loading Direction and Spacing for Group Effects

10.7.2.5—Downdrag

Design structures to tolerate the full elastic compression and pile settlement from the applied loads and drag load at the service limit state.

Since many piles are installed in groups, the horizontal resistance of the group has been studied and it has been found that multiple rows of piles will have less resistance than the sum of the single pile resistance. The front piles “shade” rows that are further back.

The P -multipliers, P_m , in Table 10.7.2.4-1 are a function of the center-to-center (CTC) spacing of piles in the group in the direction of loading expressed in multiples of the pile diameter, B . The values of P_m in Table 10.7.2.4-1 were developed for vertical piles only.

Lateral load tests have been performed on pile groups, and multipliers have been determined that can be used in the analysis for the various rows. Those multipliers have been found to depend on the pile spacing and the row number in the direction of loading. To establish values of P_m for other pile spacing values, interpolation between values should be conducted.

The multipliers are a topic of current research and may change in the future. Values from recent research have been tabulated by Hannigan et al. (2006).

Note that these p - y methods generally apply to foundation elements that have some ability to bend and deflect. For large diameter, relatively short foundation elements, e.g., drilled shafts or relatively short stiff piles, the foundation element rotates rather than bends, in which case strain wedge theory (Norris, 1986) (Ashour et al., 1998) may be more applicable. When strain wedge theory is used to assess the lateral load response of groups of short, large diameter piles or shaft groups, group effects should be addressed through evaluation of the overlap between shear zones formed due to the passive wedge that develops in front of each shaft in the group as lateral deflection increases. Note that P_m in Table 10.7.2.4-1 is not applicable if strain wedge theory is used.

Batter piles provide a much stiffer lateral response than vertical piles when loaded in the direction of the batter.

C10.7.2.5

Downdrag is pile settlement resulting from applied drag load, DR . Drag load acts in the region from the ground surface to the neutral plane, NP, and is caused by adjacent, relative, soil settlement.

Soil settlement, through soil–pile interface shear, causes drag load, which, in turn, causes downdrag. If the pile toe is sufficiently fixed, drag load may exist without measurable downdrag movement. Piles which are not fixed at the toe will settle more when drag load is present, as compared to cases without drag load. Drag load increases total load in the pile and causes added elastic

compression and added toe movement depending on toe fixity.

Drag load and resulting downdrag may result from a variety of geotechnical conditions including settlement of consolidating layers, compression of soil layers due to dewatering, and compaction following liquefaction events. Desired serviceability at applicable limit states, where site-specific conditions exist, should be considered in design.

For establishing settlement tolerance limits, see Article 10.5.2.1.

10.7.2.6—Lateral Squeeze

Bridge abutments supported on pile foundations driven through soft soils that are subject to unbalanced embankment fill loading shall be evaluated for lateral squeeze.

C10.7.2.6

Guidance on evaluating the potential for lateral squeeze and potential mitigation methods are included in Hannigan et al. (2006).

10.7.3—Strength Limit State Design

10.7.3.1—General

For strength limit state design, the following shall be determined:

- Loads and performance requirements;
- Pile type, dimensions, and nominal bearing resistance;
- Size and configuration of the pile group to provide adequate foundation support;
- Estimated pile length to be used in the construction contract documents to provide a basis for bidding;
- A minimum pile penetration, if required, for the particular site conditions and loading, determined based on the maximum (deepest) depth needed to meet all of the applicable requirements identified in Article 10.7.6;
- The maximum driving resistance expected in order to reach the minimum pile penetration required, if applicable, including any soil/pile side resistance that will not contribute to the long-term nominal bearing resistance of the pile, e.g., soil that will be removed by scour;
- The drivability of the selected pile to achieve the required nominal axial resistance or minimum penetration with acceptable driving stresses at a satisfactory blow count per unit length of penetration; and
- The nominal structural resistance of the pile and/or pile group.

Overall stability of a pile supported foundation shall be evaluated where:

C10.7.3.1

A minimum pile penetration should only be specified if needed to ensure that uplift, lateral stability, depth to satisfy scour concerns, and depth for structural lateral resistance are met for the strength limit state, in addition to similar requirements for the service and extreme event limit states. See Article 10.7.6 for additional details. Assuming static load tests, dynamic methods, e.g., dynamic test with signal matching, wave equation, and pile formulas, are used during pile installation to establish when the nominal bearing resistance has been met, a minimum pile penetration should not be used to ensure that the required nominal pile bearing, i.e., compression, resistance is obtained.

A nominal resistance measured during driving exceeding the compressive nominal resistance required by the contract may be needed to reach a minimum pile penetration specified in the contract.

The drivability analysis is performed to establish whether a hammer and driving system will likely install the pile in a satisfactory manner.

- the foundation is placed through an embankment,
- the pile foundation is located on, near or within a slope,
- the possibility of loss of foundation support through erosion or scour exists, or
- bearing strata are significantly inclined.

Unbalanced lateral loads caused by lack of overall stability or lateral squeeze should be mitigated through stabilization measures to prevent failure of the foundation, structure, and what the foundation supports.

10.7.3.2—Point Bearing Piles on Rock

10.7.3.2.1—General

As applied to pile compressive resistance, this Article shall be considered applicable to soft rock, hard rock, and very strong soils such as very dense glacial tills that will provide high nominal bearing resistance in compression with little penetration.

C10.7.3.2.1

If pile penetration into rock is expected to be minimal, the prediction of the required pile length will usually be based on the depth to rock.

A definition of hard rock that relates to measurable rock characteristics has not been widely accepted. Local or regional experience with driving piles to rock provides the most reliable definition.

In general, it is not practical to drive piles into rock to obtain significant uplift or lateral resistance. The ability to obtain sufficient uplift resistance will depend on the softness of the rock formation. Local experience should also be considered. If significant lateral or uplift foundation resistance is required, drilled shaft foundations should be considered. If it is still desired to use piles, a pile drivability study should be performed to verify the feasibility of obtaining the desired penetration into rock.

10.7.3.2.2—Piles Driven to Soft Rock

Soft rock that can be penetrated by pile driving shall be treated in the same manner as soil for the purpose of design for bearing resistance, in accordance with Article 10.7.3.8.

C10.7.3.2.2

Steel piles driven into soft rock may not require tip protection.

10.7.3.2.3—Piles Driven to Hard Rock

The nominal resistance of piles driven to point bearing on hard rock where pile penetration into the rock formation is minimal is controlled by the structural limit state. The nominal bearing resistance shall not exceed the values obtained from Article 6.9.4.1 with the resistance factors specified in Article 6.5.4.2 and Article 6.15 for severe driving conditions. A pile-driving acceptance criteria shall be developed that will prevent pile damage. Dynamic pile measurements should be used to monitor for pile damage.

C10.7.3.2.3

Care should be exercised in driving piles to hard rock to avoid tip damage. The tips of steel piles driven to hard rock should be protected by high strength, cast steel tip protection.

If the rock surface is reasonably flat, installation with pile tip protection should be considered. In the case of sloping rock, or when battered piles are driven to rock, greater difficulty can arise and the use of tip protection with teeth should be considered. The designer should perform a wave equation analysis to check anticipated stresses, and also consider the following to minimize the risk of pile damage during installation:

- Use a relatively small hammer. If a hammer with an adjustable stroke or energy setting is used, it should be operated with a small stroke to seat the pile. The

nominal axial resistance can then be proven with a few larger hammer blows.

- A large hammer should not be used if it cannot be adjusted to a low stroke. It may be impossible to detect possible toe damage if a large hammer with large stroke is used.
- For any hammer size, specify a limited number of hammer blows after the pile tip reaches the rock, and stop immediately. An example of a limiting criteria is five blows per one-half inch.
- Extensive dynamic testing can be used to verify bearing resistance on a large percentage of the piles. This approach could be used to justify larger design nominal resistances.

If such measures are taken, and successful local experience is available, it may be acceptable to not conduct the dynamic pile measurements.

10.7.3.3—Pile Length Estimates for Contract Documents

Subsurface geotechnical information combined with static analysis methods (see Article 10.7.3.8.6), preconstruction probe pile programs (see Article 10.7.9), and/or pile load tests (see Article 10.7.3.8.2) shall be used to estimate the depth of penetration required to achieve the desired nominal bearing resistance to establish contract pile quantities. If static analysis methods are used, potential bias in the method selected should be considered when estimating the penetration depth required to achieve the desired nominal bearing resistance. Local pile driving experience shall also be considered when making pile quantity estimates. If the depth of penetration required to obtain the desired nominal bearing, i.e., compressive resistance is less than the depth required to meet the provisions of Article 10.7.6, the minimum penetration required per Article 10.7.6 should be used as the basis for estimating contract pile quantities.

C10.7.3.3

The estimated pile length necessary to provide the required nominal resistance is determined using a static analysis, local pile driving experience, knowledge of the site subsurface conditions, and/or results from a static pile load test program. The required pile length is often defined by the presence of an obvious bearing layer. Local pile driving experience with such a bearing layer should be strongly considered when developing pile quantity estimates.

In variable soils, a program of probe piles across the site is often used to determine variable pile order lengths. Probe piles are particularly useful when driving concrete piles. The pile penetration depth (i.e., length) used to estimate quantities for the contract should also consider requirements to satisfy other design considerations, including service and extreme event limit states, as well as minimum pile penetration requirements for lateral stability, uplift, scour, group settlement, etc.

One solution to the problem of predicting pile length is the use of a preliminary test program at the site. Such a program can range from a very simple operation of driving a few piles to evaluate drivability, to an extensive program where different pile types are driven and static load and dynamic testing is performed. For large projects, such test programs may be very cost effective.

In lieu of local pile driving experience, if a static analysis method is used to estimate the pile length required to achieve the desired nominal resistance for establishment of contract pile quantities, to theoretically account for method bias, the factored resistance used to determine the number of piles required in the pile group may be conservatively equated to the factored resistance estimated using the static analysis method as follows:

$$\phi_{dyn} \times R_n = \phi_{stat} \times R_{nstat} \quad (C10.7.3.3-1)$$

where:

- Φ_{dyn} = the resistance factor for the dynamic method used to verify pile bearing resistance during driving, specified in Table 10.5.5.2.3-1
- R_n = the nominal pile bearing resistance (kips)
- Φ_{stat} = the resistance factor for the static analysis method used to estimate the pile penetration depth required to achieve the desired bearing resistance, specified in Table 10.5.5.2.3-1
- R_{nstat} = the predicted nominal resistance from the static analysis method used to estimate the penetration depth required (kips)

Using Eq. C10.7.3.3-1 and solving for R_{nstat} , use the static analysis method to determine the penetration depth required to obtain R_{nstat} .

The resistance factor for the static analysis method inherently accounts for the bias and uncertainty in the static analysis method. However, local experience may dictate that the penetration depth estimated using this approach be adjusted to reflect that experience. Where piles are driven to a well-defined firm bearing stratum, the location of the top of bearing stratum will dictate the pile length needed, and Eq. C10.7.3.3-1 is likely not applicable.

Note that R_n is considered to be nominal bearing resistance of the pile needed to resist the applied loads, and is used as the basis for determining the resistance to be achieved during pile driving, R_{ndr} (see Articles 10.7.6 and 10.7.7). R_{nstat} is only used in the static analysis method to estimate the pile penetration depth required.

Note that while there is a theoretical basis to this suggested approach, it can produce apparently erroneous results if attempting to use extremes in static analysis and dynamic methods, e.g., using static load test results and then using the EN formula to control pile driving, or using a very inaccurate static analysis method in combination with dynamic testing and signal matching. Part of the problem is that the available resistance factors have been established in consideration of the risk and consequences of pile foundation failure rather than the risk and consequences of underrunning or overrunning pile quantities. Therefore, the approach provided in Eq. C10.7.3.3-1 should be used cautiously, especially when the difference between the resistance factors for method used to estimate pile penetration depth versus the one used for obtaining the required nominal axial resistance is large.

10.7.3.4—Nominal Axial Resistance Change after Pile Driving

10.7.3.4.1—General

Consideration should be given to the potential for change in the nominal axial pile resistance after the end of pile driving. The effect of soil relaxation or setup

C10.7.3.4.1

Soil relaxation is not a common phenomenon but more serious than setup since it represents a reduction in the reliability of the foundation.

should be considered in the determination of nominal axial pile resistance for soils that are likely to be subject to these phenomena.

10.7.3.4.2—Relaxation

If relaxation is possible in the soils at the site the pile shall be tested in restrike after a sufficient time has elapsed for relaxation to develop.

10.7.3.4.3—Setup

Setup in the nominal axial resistance may be used to support the applied load. Where increase in resistance due to setup is utilized, the existence of setup shall be verified after a specified length of time by re-striking the pile.

Soil setup is a common phenomenon that can provide the opportunity for using larger nominal resistances at no increase in cost. However, it is necessary that the resistance gain be adequately proven. This is usually accomplished by restrike testing with dynamic measurements (Komurka et al., 2003).

C10.7.3.4.2

Relaxation is a reduction in axial pile resistance. While relaxation typically occurs at the pile tip, it can also occur along the sides of the pile (Morgano and White, 2004). It can occur in dense sands or sandy silts and in some shales. Relaxation in the sands and silts will usually develop fairly quickly after the end of driving (perhaps in only a few minutes or hours) as a result of the return of the reduced pore pressure induced by dilation of the dense sands during driving. In some shales, relaxation occurs during the driving of adjacent piles and that will be immediate. There are other shales where the pile penetrates the shale and relaxation requires perhaps as much as two weeks to develop. In some cases, the amount of relaxation can be large.

C10.7.3.4.3

Setup is an increase in the nominal axial resistance that develops over time predominantly along the pile shaft. Pore pressures increase during pile driving due to a reduction of the soil volume, reducing the effective stress and the shear strength. Setup may occur rapidly in cohesionless soils and more slowly in finer grained soils as excess pore water pressures dissipate. In some clays, setup may continue to develop over a period of weeks and even months, and in large pile groups it can develop even more slowly.

Setup, sometimes called “pile freeze,” can be used to carry applied load, providing the opportunity for using larger pile nominal axial resistances, if it can be proven. Signal matching analysis of dynamic pile measurements made at the end of driving and later in restrike can be an effective tool in evaluating and quantifying setup. (Komurka et al., 2003) (Bogard and Matlock, 1990).

If a wave equation or dynamic formula is used to determine the nominal pile bearing resistance on restrike, care should be used as these approaches require accurate blow count measurement which is inherently difficult at the BOR. Furthermore, the resistance factors provided in Table 10.5.5.2.3-1 for driving formulas were developed for end of driving conditions and empirically have been developed based on the assumption that soil setup will occur. See Article C10.5.5.2.3 for additional discussion on this issue.

Higher degrees of confidence for the assessment of setup effects are provided by dynamic measurements of pile driving with signal matching analyses or static load tests after a sufficient wait time following pile installation.

The restrike time and frequency should be based on the time dependent strength change characteristics of the soil. The following restrike durations are recommended:

Soil Type	Time Delay until Restrike
Clean Sands	1 day
Silty Sands	2 days
Sandy Silts	3–5 days
Silts and Clays	7–14 days*
Shales	7 days

* Longer times are sometimes required.

Specifying a restrike time for friction piles in fine-grained soils which is too short may result in pile length overruns.

10.7.3.5—Groundwater Effects and Buoyancy

Nominal axial resistance shall be determined using the groundwater level consistent with that used to calculate the effective stress along the pile sides and tip. The effect of hydrostatic pressure shall be considered in the design.

C10.7.3.5

Unless the pile is bearing on rock, the bearing resistance is primarily dependent on the effective surcharge that is directly influenced by the groundwater level. For drained loading conditions, the vertical effective stress is related to the groundwater level and thus it affects pile axial resistance. Lateral resistance may also be affected.

Buoyant forces may also act on a hollow pile or unfilled casing if it is sealed so that water does not enter the pile. During pile installation, this may affect the driving resistance (blow count) observed, especially in very soft soils.

For design purposes, anticipated changes in the groundwater level during construction and over the life of the structure should be considered with regard to its effect on pile resistance and constructability.

10.7.3.6—Scour

The effect of scour shall be considered in determining the minimum pile embedment and the required nominal driving resistance, R_{ndr} . The pile foundation shall be designed so that the pile penetration after soil has been removed due to the scour design flood satisfies the required nominal axial and lateral resistance.

C10.7.3.6

The piles will need to be driven to the required nominal bearing resistance plus the side resistance that will be lost due to scour. The nominal resistance of the remaining soil is determined through field verification. The pile is driven to the required nominal bearing resistance plus the magnitude of the side resistance lost as a result of scour, considering the prediction method bias. Bias is defined as the measured/predicted value of resistance, in this case pile side resistance. Typically, the average method bias, based on available databases should be used. This bias can be based on a national database, or based on a local database, if enough measurements are available to reliably establish an average value. Example bias values for various pile static resistance prediction methods based on a national database are provided in Paikowsky et al. (2004) and Allen (2005).

To use bias values to adjust pile resistance predictions, since a bias greater than 1.0 means the method predicts less resistance than is actually present and a bias less than 1.0 means that the method predicts more resistance than is actually present, the bias-adjusted resistance is determined by multiplying the resistance lost

The resistance factors shall be those used in the design without scour. The side resistance of the material lost due to scour should be determined using a static analysis and it should not be factored, but consideration should be given to the bias of the static analysis method used to predict resistance.

The pile foundation shall be designed to resist debris loads occurring during the flood event in addition to the loads applied from the structure.

10.7.3.7—Drag Load

The foundation should be designed with zero drag load at the geotechnical strength limit state, i.e., $DR = 0$. Where the pile is bearing on very dense soil or rock, and downward toe movement of the pile cannot occur in response to the settlement of the surrounding soil, the pile foundation shall be designed to structurally resist the drag load plus structure loads at all appropriate structural limit states.

due to scour by the bias value. Since in this case the goal is to estimate lost resistance due to scour, a conservative estimate is obtained when the method predicts more resistance than is actually present.

Another approach that may be used takes advantage of dynamic measurements. In this case, the static analysis method is used to determine an estimated length. During the driving of test piles, the side resistance component of the bearing resistance of pile in the scourable material may be determined by a signal matching analysis of the restrike dynamic measurements obtained when the pile tip is below the scour elevation. The material below the scour elevation must provide the required nominal resistance after scour occurs.

In some cases, the flooding stream will carry debris such as wood or ice that will induce horizontal loads on the piles.

Additional information regarding pile design for scour is provided in Hannigan et al. (2016).

C10.7.3.7

At the geotechnical strength limit state, all geotechnical resistance is fully mobilized. The neutral plane moves from the initial position toward the ground surface and all soil resistance becomes available to resist the downward movement of the pile. Because of the relative movement between the pile and the adjacent ground, the entire pile experiences side resistance in the positive direction (acting upward) and the drag load is reduced to zero.

At the geotechnical strength limit state, a pile subjected to drag load is identical to one without drag load and nominal resistance may be estimated using the static analysis methods specified in Article 10.7.3.8.6 or from restrike signal matching analysis, driving formulas, or instrumented static pile load test results. Note that the static analysis methods may have bias that, on average, over or under predicts the side resistance. The bias of the method selected to estimate the skin friction should be considered as described in Article C10.7.3.3.

The drag load is largest when a pile has relatively little downward movement relative to the settling surrounding soil or the surrounding soil has large relative settlement. These conditions often exist at the service limit or extreme event limit states. When calculating drag load effects, the designer should not ignore soil layers, even if they are thought not to contribute materially to available resistance to support structural loads (e.g. piles through soft/loose deposits end bearing on rock) as these layers may contribute very large drag load under certain conditions.

10.7.3.8—Determination of Nominal Bearing Resistance for Piles

10.7.3.8.1—General

Nominal pile bearing resistance should be field-verified during pile installation using static load tests, dynamic tests, wave equation analysis, or dynamic formula. The resistance factor selected for design shall be based on the method used to verify pile bearing resistance as specified in Article 10.5.5.2.3. The production piles shall be driven to the minimum blow count determined from the static load test, dynamic test, wave equation, or dynamic formula and, if required, to a minimum penetration needed for uplift, scour, lateral resistance, or other requirements as specified in Article 10.7.6. If it is determined that static load testing is not feasible and dynamic methods are unsuitable for field verification of nominal bearing resistance, the piles shall be driven to the tip elevation determined from the static analysis, and to meet other limit states as required in Article 10.7.6.

10.7.3.8.2—Static Load Test

If a static pile load test is used to determine the pile nominal axial resistance, the test shall not be performed less than five days after the test pile was driven unless approved by the Engineer. The load test shall follow the procedures specified in ASTM D1143, and the loading procedure should follow the Quick Load Test Procedure.

Unless specified otherwise by the Engineer, the nominal bearing resistance shall be determined from the test data as follows:

- for piles 24.0 in. or less in diameter (length of side for square piles), the Davisson method;
- for piles larger than 36.0 in. in diameter (length of side for square piles), at a pile top movement, s_f (in.), as determined from Eq. 10.7.3.8.2-1; and
- for piles greater than 24.0 in. but less than 36.0 in. in diameter, criteria to determine the nominal bearing resistance that is linearly interpolated between the criteria determined at diameters of 24.0 and 36.0 in.

$$s_f = \frac{QL}{12AE} + \frac{B}{2.5} \quad (10.7.3.8.2-1)$$

where:

- Q = test load (kips)
- L = pile length (ft)
- A = pile cross-sectional area (ft²)
- E = pile modulus (ksi)
- B = pile diameter (length of side for square piles) (ft)

C10.7.3.8.1

This Article addresses the determination of the nominal bearing (compression) resistance needed to meet strength limit state requirements, using factored loads and factored resistance values. From this design step, the number of piles and pile nominal resistance needed to resist the factored loads applied to the foundation are determined. Both the loads and resistance values are factored as specified in Articles 3.4.1 and 10.5.5.2.3, respectively, for this determination.

In most cases, the nominal resistance of production piles should be controlled by driving to a required blow count. In a few cases, usually piles driven into cohesive soils with little or no toe resistance and very long wait times to achieve the full pile resistance increase due to soil setup, piles may be driven to depth. However, even in those cases, a pile may be selected for testing after a sufficient waiting period, using either a static load test or a dynamic test.

In cases where the project is small and the time to achieve soil setup is large compared with the production time to install all of the piles, no field testing for the verification of nominal resistance may be acceptable.

C10.7.3.8.2

The Quick Load Test Procedure is preferred because it avoids problems that frequently arise when performing a static load test that cannot be completed within an eight-hour period. Tests that extend over a longer period are difficult to perform due to the limited number of experienced personnel that are usually available. The Quick Load Test has proven to be easily performed in the field and the results usually are satisfactory. Static load tests should be conducted to failure whenever possible and practical to extract the maximum information, particularly when correlating with dynamic tests or static analysis methods. However, if the formation in which the pile is installed may be subject to significant creep settlement, alternative procedures provided in ASTM D1143 should be considered.

The Davisson Method to determine nominal bearing resistance evaluation is performed by constructing a line on the static load test curve that is parallel to the elastic compression line of the pile. The elastic compression line is calculated by assuming equal compressive forces are applied to the pile ends. The elastic compression line is offset by a specified amount of displacement. The Davisson Method is illustrated in Figure C10.7.3.8.2-1 and described in more detail in Hannigan et al. (2006).

Driving criteria should be established in consideration of the static load test results.

Figure C10.7.3.8.2-1—Alternate Method Load Test Interpretation (Cheney and Chassie, 2000, modified after Davisson, 1972) Note: The failure criterion, X , is in feet in this figure.

For piles with large cross-sections, i.e., diameters greater than 24.0 in., the Davisson Method will under predict the nominal pile bearing resistance.

Development of driving criteria in consideration of static load test results is described in Hannigan et al. (2006).

10.7.3.8.3—Dynamic Testing

Dynamic testing shall be performed according to the procedures given in ASTM D4945. If possible, the dynamic test should be performed as a restrike test if the Engineer anticipates significant time dependent strength change. The nominal pile bearing resistance shall be determined by a signal matching analysis of the dynamic pile test data if the dynamic test is used to establish the driving criteria.

C10.7.3.8.3

The dynamic test may be used to establish the driving criteria at the beginning of production driving. A signal matching analysis (Rausche et al., 1972) of the dynamic test data should always be used to determine bearing resistance if a static load test is not performed. See Hannigan et al. (2006) for a description of and procedures to conduct a signal matching analysis. Restrike testing should be performed if setup or relaxation is anticipated.

For example, note that it may not be possible to adjust the dynamic measurements with signal matching analysis to match the static load test results if the driving resistance at the time the dynamic measurement is taken is too large, i.e., the pile set per hammer blow is too small. In this case, adequate hammer energy is not reaching the pile tip to assess end bearing and produce an accurate match, though in such cases, the prediction will usually be very conservative. In general, a tip movement (pile set) of 0.10 to 0.15 in. is needed to provide an accurate signal matching analysis. See Hannigan et al. (2006) for additional guidance on this issue.

In cases where a significant amount of soil setup occurs and the set at the BOR is less than 0.10 inch per blow, a more accurate nominal resistance may be obtained by combining the end bearing determined using the signal matching analysis obtained for EOD with the signal matching analysis for the shaft resistance at the beginning of redrive.

Dynamic testing and interpretation of the test data should only be performed by certified, experienced testers.

10.7.3.8.4—Wave Equation Analysis

If a wave equation analysis is to be used to establish the driving criteria, it shall be performed based on the hammer and pile driving system to be used for pile installation.

If a wave equation analysis is used for the determination of the nominal bearing resistance, then the driving criterion (blow count) may be the value taken either at the EOD or at BOR. The latter should be used where the soils exhibit significant strength changes (setup or relaxation) with time. When restrike (i.e., BOR) blow counts are taken, the hammer shall be warmed up prior to restrike testing and the blow count shall be taken as accurately as possible for the first inch of restrike.

If the wave equation is used to assess the potential for pile damage, driving stresses shall not exceed the values obtained in Article 10.7.8, using the resistance factors specified or referred to in Table 10.5.5.2.3-1. Furthermore, the blow count needed to obtain the maximum driving resistance anticipated shall be less than the maximum value established based on the provisions in Article 10.7.8.

C10.7.3.8.4

Note that without dynamic test results with signal matching analysis and/or pile load test data (see Articles 10.7.3.8.2 and 10.7.3.8.3), some judgment is required to use the wave equation to predict the pile bearing resistance. Unless experience in similar soils exists, the recommendations of the software provider should be used for dynamic resistance input. Key soil input values that affect the predicted nominal resistance include the soil damping and quake values, the skin friction distribution, e.g., such as could be obtained from a static pile bearing analysis, and the anticipated amount of soil setup or relaxation. The actual hammer performance is a variable that can only be accurately assessed through dynamic measurements, though field observations such as hammer stroke or measured ram velocity can and should be used to improve the accuracy of the wave equation prediction.

In general, improved prediction accuracy of nominal bearing resistance is obtained when targeting the driving criteria at BOR conditions, if soil setup or relaxation is anticipated. Using the wave equation to predict nominal bearing resistance from EOD blow counts requires that an accurate estimate of the time-dependent changes in bearing resistance due to soil setup or relaxation be made. This is generally difficult to do unless site-specific, longer-term measurements of bearing resistance from static load tests or dynamic measurements with signal matching are available. Hence, driving criteria based on BOR measurements are recommended when using the wave equation for driving criteria development.

A wave equation analysis should also be used to evaluate pile drivability during design.

10.7.3.8.5—Dynamic Formula

If a dynamic formula is used to establish the driving criterion, the FHWA Gates formula (Eq. 10.7.3.8.5-1) should be used. The nominal pile resistance as measured during driving using this method shall be taken as:

$$R_{ndr} = 1.75\sqrt{E_d} \log_{10}(10N_b) - 100 \quad (10.7.3.8.5-1)$$

where:

- R_{ndr} = nominal pile driving resistance measured during pile driving (kips)
- E_d = developed hammer energy. This is the kinetic energy in the ram at impact for a given blow. If ram velocity is not measured, it may be assumed equal to the potential energy of the ram at the height of the stroke, taken as the ram weight times the actual stroke (ft-lb)
- N_b = Number of hammer blows for 1.0 in. of pile permanent set (blows/in.)

C10.7.3.8.5

It is preferred to use more accurate methods such as wave equation or dynamic testing with signal matching to establish driving criteria (i.e., blow count). However, driving formulas have been in use for many years. Therefore, driving formulas are provided as an option for the development of driving criteria.

Two dynamic formulas are provided here for the Engineer. If a dynamic formula is used for either determination of the nominal resistance or the driving criterion, the FHWA Modified Gates formula is preferred over the EN formula. It is discussed further in *Design and Construction of Driven Pile Foundations* (Hannigan et al., 2006). Note that the units in the FHWA Gates formula are not consistent. The specified units in Eq. 10.7.3.8.5-1 must be used.

The EN formula in its traditional form contains a factor of safety of 6.0. For LRFD applications, to produce a nominal resistance, the factor of safety has been removed. As is true of the FHWA Gates formula, the units specified in Eq. 10.7.3.8.5-2 must be used for the EN formula. See Allen (2005; 2007) for additional

The EN formula, modified to predict a nominal bearing resistance, may be used. The nominal pile resistance using this method shall be taken as:

$$R_{ndr} = \frac{12E_d}{(s + 0.1)} \quad (10.7.3.8.5-2)$$

where:

- R_{ndr} = nominal pile resistance measured during driving (kips)
- E_d = developed hammer energy. This is the kinetic energy in the ram at impact for a given blow. If ram velocity is not measured, it may be assumed equal to the potential energy of the ram at the height of the stroke, taken as the ram weight times the stroke (ft-kips)
- s = pile permanent set (in.)

If a dynamic formula other than those provided herein is used, it shall be calibrated based on measured load test results to obtain an appropriate resistance factor, consistent with Article C10.5.5.2.

If a drivability analysis is not conducted, for steel piles, design stresses shall be limited as specified in Article 6.15.2.

Dynamic formulas should not be used when the required nominal resistance exceeds 600 kips.

discussion on the development of the EN formula and its modification to produce a nominal resistance.

Driving formula should only be used to determine end of driving blow count criteria. These driving formula are empirically based on pile load test results, and therefore inherently include some degree of soil setup or relaxation (see Allen, 2007).

As the required nominal bearing resistance increases, the reliability of dynamic formulas tends to decrease. The FHWA Gates formula tends to underpredict pile nominal resistance at higher resistances. The EN formula tends to become unconservative as the nominal pile resistance increases. If other driving formulas are used, the limitation on the maximum driving resistance to be used should be based upon the limits for which the data is considered reliable, and any tendency of the formula to over or under predict pile nominal resistance.

10.7.3.8.6—Static Analysis

10.7.3.8.6a—General

Where a static analysis prediction method is used to determine pile installation criteria, i.e., for bearing resistance, the nominal pile resistance shall be factored at the strength limit state using the resistance factors in Table 10.5.5.2.3-1 associated with the method used to compute the nominal bearing resistance of the pile. The factored nominal bearing resistance of piles, R_R , may be taken as:

$$R_R = \phi R_n \quad (10.7.3.8.6a-1)$$

or:

$$R_R = \phi R_n = \phi_{stat} R_p + \phi_{stat} R_s \quad (10.7.3.8.6a-2)$$

in which:

C10.7.3.8.6a

While the most common use of static analysis methods is solely for estimating pile quantities, a static analysis may be used to establish pile installation criteria if dynamic methods are determined to be unsuitable for field verification of nominal bearing resistance. This is applicable on projects where pile quantities are relatively small, pile loads are relatively low, and/or where the setup time is long so that restrike testing would require an impractical wait-period by the Contractor on the site, e.g., soft silts or clays where a large amount of setup is anticipated.

For use of static analysis methods for contract pile quantity estimation, see Article 10.7.3.3.

$$R_p = q_p A_p \quad (10.7.3.8.6a-3)$$

$$R_s = q_s A_s \quad (10.7.3.8.6a-4)$$

where:

ϕ_{stat} = resistance factor for the bearing resistance of a single pile, specified in Article 10.5.5.2.3

R_p = pile tip resistance (kips)

R_s = pile side resistance (kips)

q_p = unit tip resistance of pile (ksf)

q_s = unit side resistance of pile (ksf)

A_s = surface area of pile side (ft²)

A_p = area of pile tip (ft²)

Both total stress and effective stress methods may be used, provided the appropriate soil strength parameters are available. The resistance factors for the side resistance and tip resistance, estimated using these methods, shall be as specified in Table 10.5.5.2.3-1. The limitations of each method as described in Article C10.5.5.2.3 should be applied in the use of these static analysis methods.

10.7.3.8.6b— α -Method

The α -method, based on total stress, may be used to relate the adhesion between the pile and clay to the undrained strength of the clay. For this method, the nominal unit side resistance, in ksf, shall be taken as:

$$q_s = \alpha S_u \quad (10.7.3.8.6b-1)$$

where:

S_u = undrained shear strength (ksf)

α = adhesion factor applied to S_u (dim)

The adhesion factor for this method, α , shall be assumed to vary with the value of the undrained strength, S_u , as shown in Figure 10.7.3.8.6b-1.

C10.7.3.8.6b

The α -method has been used for many years and gives reasonable results for both displacement and nondisplacement piles in clay.

In general, this method assumes that a mean value of S_u will be used. It may not always be possible to establish a mean value, as in many cases, data are too limited to reliably establish the mean value. The Engineer should apply engineering judgment and local experience as needed to establish an appropriate value for design (see Article C10.4.6).

For H-piles, the perimeter or “box” area should generally be used to compute the surface area of the pile side.

Figure 10.7.3.8b-1—Design Curves for Adhesion Factors for Piles Driven into Clay Soils after Tomlinson (1980)

10.7.3.8.6c— β -Method

The β -method, based on effective stress, may be used for predicting side resistance of prismatic piles. The nominal unit skin friction for this method, in ksf, shall be related to the effective stresses in the ground as:

$$q_s = \beta \sigma'_v \quad (10.7.3.8.6c-1)$$

where:

σ'_v = vertical effective stress (ksf)

β = a factor taken from Figure 10.7.3.8.6c-1

C10.7.3.8.6c

The β -method has been found to work best for piles in normally consolidated and lightly overconsolidated clays. The method tends to overestimate side resistance of piles in heavily overconsolidated soils. Esrig and Kirby (1979) suggested that for heavily overconsolidated clays, the value of β should not exceed two.

Figure 10.7.3.8.6c-1— β Versus OCR for Displacement Piles after Esrig and Kirby (1979)

10.7.3.8.6d— λ -Method

The λ -method, based on effective stress (though it does contain a total stress parameter), may be used to relate the unit side resistance, in ksf, to passive earth pressure. For this method, the unit skin friction shall be taken as:

$$q_s = \lambda(\sigma'_v + 2S_u) \quad (10.7.3.8.6d-1)$$

where:

- $\sigma'_v + 2S_u$ = passive lateral earth pressure (ksf)
- σ'_v = the effective vertical stress at midpoint of soil layer under consideration (ksf)
- λ = empirical coefficient taken from Figure 10.7.3.8.6d-1 (dim)

C10.7.3.8.6d

The value of λ decreases with pile length and was found empirically by examining the results of load tests on steel pipe piles.

Figure 10.7.3.8.6d-1— λ Coefficient for Driven Pipe Piles after Vijayvergiya and Focht (1972)

10.7.3.8.6e—Tip Resistance in Cohesive Soils

The nominal unit tip resistance of piles in saturated clay, in ksf, shall be taken as:

$$q_p = 9S_u \quad (10.7.3.8.6e-1)$$

where:

S_u = undrained shear strength of the clay near the pile tip (ksf)

10.7.3.8.6f—Nordlund/Thurman Method in Cohesionless Soils

C10.7.3.8.6f

This effective stress method should be applied only to sands and nonplastic silts. The nominal unit side resistance, q_s , for this method, in ksf, shall be taken as:

$$q_s = K_\delta C_F \sigma'_v \frac{\sin(\delta + \omega)}{\cos \omega} \quad (10.7.3.8.6f-1)$$

where:

K_δ = coefficient of lateral earth pressure at mid-point of soil layer under consideration from Figures 10.7.3.8.6f-1 through 10.7.3.8.6f-4 (dim)

Detailed design procedures for the Nordlund/Thurman method are provided in Hannigan et al. (2006). This method was derived based on load test data for piles in sand. In practice, it has been used for gravelly soils as well.

The effective overburden stress is not limited in Eq. 10.7.3.8.6f-1.

For H-piles, the perimeter or “box” area should generally be used to compute the surface area of the pile side.

- C_F = correction factor for K_δ when $\delta \neq \phi_f$, from Figure 10.7.3.8.6f-5
 σ'_v = effective overburden stress at midpoint of soil layer under consideration (ksf)
 δ = friction angle between pile and soil obtained from Figure 10.7.3.8.6f-6 (degrees)
 ω = angle of pile taper from vertical (degrees)

Figure 10.7.3.8.6f-1—Design Curve for Evaluating K_δ for Piles where $\phi_f = 25$ degrees (Hannigan et al., 2006 after Nordlund, 1979)

Figure 10.7.3.8.6f-2—Design Curve for Evaluating K_δ for Piles where $\phi_f = 30$ degrees (Hannigan et al., 2006 after Nordlund, 1979)

Figure 10.7.3.8.6f-3—Design Curve for Evaluating K_δ for Piles where $\phi_f = 35$ degrees (Hannigan et al., 2006 after Nordlund, 1979)

Figure 10.7.3.8.6f-4—Design Curve for Evaluating K_δ for Piles where $\phi_f = 40$ degrees (Hannigan et al., 2006 after Nordlund, 1979)

Figure 10.7.3.8.6f-5—Correction Factor for K_δ where $\delta \neq \phi_f$ (Hannigan et al., 2006 after Nordlund, 1979)

Figure 10.7.3.8.6f-6—Relation of δ/ϕ_f and Pile Displacement, V , for Various Types of Piles (Hannigan et al., 2006 after Nordlund, 1979)

The nominal unit tip resistance, q_p , in ksf by the Nordlund/Thurman method shall be taken as:

$$q_p = \alpha_t N'_q \sigma'_v \leq q_L \quad (10.7.3.8.6f-2)$$

where:

- α_t = coefficient from Figure 10.7.3.8.6f-7 (dim)
- N'_q = bearing capacity factor from Figure 10.7.3.8.6f-8
- σ'_v = effective overburden stress at pile tip (ksf)
 ≤ 3.2 ksf
- q_L = limiting unit tip resistance from Figure 10.7.3.8.6f-9

If the friction angle, ϕ_f , is estimated from average, corrected SPT blow counts, Nl_{60} , the Nl_{60} values should be averaged over the zone from the pile tip to two diameters below the pile tip.

Figure 10.7.3.8.6f-7— α_i Coefficient (Hannigan et al., 2006 modified after Bowles, 1977)

Figure 10.7.3.8.6f-8—Bearing Capacity Factor, N'_q (Hannigan et al., 2006 modified after Bowles, 1977)

Figure 10.7.3.8.6f-9—Limiting Unit Pile Tip Resistance (Hannigan et al., 2006 after Meyerhof, 1976)

10.7.3.8.6g—Using SPT or CPT in
Cohesionless Soils

C10.7.3.8.6g

These methods shall be applied only to sands and nonplastic silts.

The nominal unit tip resistance for the Meyerhof method, in ksf, for piles driven to a depth, D_b , into a cohesionless soil stratum shall be taken as:

$$q_p = \frac{0.8(N1_{60})D_b}{D} \leq q_t \quad (10.7.3.8.6g-1)$$

where:

- $N1_{60}$ = representative SPT blow count near the pile tip corrected for overburden pressure, as specified in Article 10.4.6.2.4 (blows/ft)
- D = pile width or diameter (ft)
- D_b = depth of penetration into bearing strata (ft)
- q_t = limiting pile tip resistance (ksf)

q_t shall be taken as eight times the value of $N1_{60}$ for sands and six times the value of $N1_{60}$ for nonplastic silt (ksf).

The nominal side resistance of piles in cohesionless soils for the Meyerhof method, in ksf, shall be taken as:

- For driven displacement piles:

$$q_s = \frac{\bar{N}1_{60}}{25} \quad (10.7.3.8.6g-2)$$

- For nondisplacement piles, e.g., steel H-piles:

$$q_s = \frac{\bar{N}1_{60}}{50} \quad (10.7.3.8.6g-3)$$

where:

- q_s = unit side resistance for driven piles (ksf)
- $\bar{N}1_{60}$ = average corrected SPT-blow count along the pile side (blows/ft)

Tip resistance, q_p , for the Nottingham and Schmertmann method, in ksf, shall be determined as shown in Figure 10.7.3.8.6g-1:

in which:

$$q_p = \frac{q_{c1} + q_{c2}}{2} \quad (10.7.3.8.6g-4)$$

where:

- q_{c1} = average q_c over a distance of yD below the pile tip (path a-b-c); sum q_c values in both the downward (path a-b) and upward (path b-c)

In-situ tests are widely used in cohesionless soils because obtaining good quality samples of cohesionless soils is very difficult. In-situ test parameters may be used to estimate the tip resistance and side resistance of piles.

Two frequently used in-situ test methods for predicting pile axial resistance are the SPT method (Meyerhof, 1976) and the CPT method (Nottingham and Schmertmann, 1975).

Displacement piles, which have solid sections or hollow sections with a closed end, displace a relatively large volume of soil during penetration. Nondisplacement piles usually have relatively small cross-sectional areas, e.g., steel H-piles and open-ended pipe piles that have not yet plugged. Plugging occurs when the soil between the flanges in a steel H-pile or the soil in the cylinder of an open-ended steel pipe pile adheres fully to the pile and moves down with the pile as it is driven.

CPT may be used to determine:

- The cone penetration resistance, q_c , which may be used to determine the tip resistance of piles, and
- Sleeve friction, f_s , which may be used to determine the side resistance.

directions; use actual q_c values along path a-b and the minimum path rule along path b-c; compute q_{c1} for y -values from 0.7 to 4.0 and use the minimum q_{c1} value obtained (ksf)

q_{c2} = average q_c over a distance of $8D$ above the pile tip (path c-e); use the minimum path rule as for path b-c in the q_{c1} computations; ignore any minor “x” peak depressions if in sand but include in minimum path if in clay (ksf)

The minimum average cone resistance between 0.7 and four pile diameters below the elevation of the pile tip shall be obtained by a trial and error process, with the use of the minimum-path rule. The minimum-path rule shall also be used to find the value of cone resistance for the soil for a distance of eight pile diameters above the tip. The two results shall be averaged to determine the pile tip resistance.

The nominal side resistance of piles for this method, in kips, shall be taken as:

$$R_s = K_{s,c} \left[\sum_{i=1}^{N_1} \left(\frac{L_i}{8D_i} \right) f_{si} a_{si} h_i + \sum_{i=1}^{N_2} f_{si} a_{si} h_i \right] \quad (10.7.3.8.6g-5)$$

where:

$K_{s,c}$ = correction factors: K_c for clays and K_s for sands from Figure 10.7.3.8.6g-2 (dim)

L_i = depth to middle of length interval at the point considered (ft)

D_i = pile width or diameter at the point considered (ft)

f_{si} = unit local sleeve friction resistance from CPT at the point considered (ksf)

a_{si} = pile perimeter at the point considered (ft)

h_i = length interval at the point considered (ft)

N_1 = number of intervals between the ground surface and a point $8D$ below the ground surface

N_2 = number of intervals between $8D$ below the ground surface and the tip of the pile

This process is described in Nottingham and Schmertmann (1975).

For a pile of constant cross-section (nontapered), Eq. 10.7.3.8.6g-5 can be written as:

$$R_s = K_{s,c} \left[\frac{a_s}{8D} \sum_{i=1}^{N_1} L_i f_{si} h_i + a_s \sum_{i=1}^{N_2} f_{si} h_i \right] \quad (C10.7.3.8.6g-1)$$

If, in addition to the pile being prismatic, f_s is approximately constant at depths below $8D$, Eq. C10.7.3.8.6g-1 can be simplified to:

$$R_s = K_{s,c} [a_s f_s (Z - 4D)] \quad (C10.7.3.8.6g-2)$$

where:

Z = total embedded pile length (ft)

Figure 10.7.3.8.6g-2 —Side Resistance Correction Factors K_s and K_c after Nottingham and Schmertmann (1975)

10.7.3.9—Resistance of Pile Groups in Compression

For pile groups in clay, the nominal bearing resistance of the pile group shall be taken as the lesser of:

- the sum of the individual nominal resistances of each pile in the group, or
- the nominal resistance of an equivalent pier consisting of the piles and the block of soil within the area bounded by the piles.

If the cap is not in firm contact with the ground and if the soil at the surface is soft, the individual nominal resistance of each pile shall be multiplied by an efficiency factor η , taken as:

- $\eta = 0.65$ for a center-to-center spacing of 2.5 diameters, and
- $\eta = 1.0$ for a center-to-center spacing of 6.0 diameters.

For intermediate spacings, the value of η should be determined by linear interpolation.

If the cap is in firm contact with the ground, no reduction in efficiency shall be required. If the cap is not in firm contact with the ground and if the soil is stiff, no reduction in efficiency shall be required.

The nominal bearing resistance of pile groups in cohesionless soil shall be the sum of the resistance of all the piles in the group. The efficiency factor, η , shall be 1.0 where the pile cap is or is not in contact with the ground for a center-to-center pile spacing of 2.5 diameters or

C10.7.3.9

The equivalent pier approach checks for block failure and is generally only applicable for pile groups within cohesive soils. For pile groups in cohesionless soils, the sum of the nominal resistances of the individual piles always controls the group resistance.

When analyzing the equivalent pier, the full shear strength of the soil should be used to determine the friction resistance. The total base area of the equivalent pier should be used to determine the end bearing resistance.

In cohesive soils, the nominal resistance of a pile group depends on whether the cap is in firm contact with the ground beneath. If the cap is in firm contact, the soil between the pile and the pile group behave as a unit.

At small pile spacings, a block type failure mechanism may prevail, whereas individual pile failure may occur at larger pile spacings. It is necessary to check for both failure mechanisms and design for the case that yields the minimum capacity.

For a pile group of width X , length Y , and depth Z , as shown in Figure C10.7.3.9-1, the bearing capacity for block failure, Q_g , in kips, is given by:

$$Q_g = (2X + 2Y) Z \bar{S}_u + X Y N_c S_u \quad (\text{C10.7.3.9-1})$$

in which:

$$\text{for } \frac{Z}{X} \leq 2.5:$$

greater. The resistance factor is the same as that for single piles, as specified in Table 10.5.5.2.3-1.

For pile groups in clay or sand, if a pile group is tipped in a strong soil deposit overlying a weak deposit, the block bearing resistance shall be evaluated with consideration to pile group punching as a group into the underlying weaker layer. The methods in Article 10.6.3.1.2a of determining bearing resistance of a spread footing in a strong layer overlying a weaker layer shall apply, with the notional footing located as shown in Article 10.7.2.3.

$$N_c = 5 \left(1 + \frac{0.2X}{Y} \right) \left(1 + \frac{0.2Z}{X} \right) \quad (\text{C10.7.3.9-2})$$

for $\frac{Z}{X} > 2.5$:

$$N_c = 7.5 \left(1 + \frac{0.2X}{Y} \right) \quad (\text{C10.7.3.9-3})$$

where:

$\bar{S}_u$ = average undrained shear strength along the depth of penetration of the piles (ksf)

S_u = undrained shear strength at the base of the group (ksf)

Figure C10.7.3.9-1—Pile Group Acting as a Block Foundation

10.7.3.10—Uplift Resistance of Single Piles

Uplift on single piles shall be evaluated when tensile forces are present. The factored nominal tensile resistance of the pile due to soil failure shall be greater than the factored pile loads.

The nominal uplift resistance of a single pile should be estimated in a manner similar to that for estimating the side resistance of piles in compression specified in Article 10.7.3.8.6.

Factored uplift resistance in kips shall be taken as:

$$R_R = \phi R_n = \phi_{up} R_s \quad (10.7.3.10-1)$$

C10.7.3.10

The factored load effect acting on any pile in a group may be estimated using the traditional elastic strength of materials procedure for a cross-section under thrust and moment. The cross-sectional properties should be based on the pile as a unit area.

Note that the resistance factor for uplift already is reduced to 80 percent of the resistance factor for static side resistance. Therefore, the side resistance estimated based on Article 10.7.3.8.6 does not need to be reduced to account for uplift effects on side resistance.

The nominal group uplift resistance may be taken as:

$$R_n = R_{ug} = (2XZ + 2YZ)\bar{S}_u + W_g \quad (10.7.3.11-2)$$

where:

- X = width of the group, as shown in Figure 10.7.3.11-2 (ft)
- Y = length of the group, as shown in Figure 10.7.3.11-2 (ft)
- Z = depth of the block of soil below pile cap taken from Figure 10.7.3.11-2 (ft)
- $\bar{S}_u$ = average undrained shear strength along the sides of the pile group (ksf)
- W_g = weight of the block of soil, piles, and pile cap (kips)

The resistance factor for the nominal group uplift resistance, R_{ug} , determined as the sum of the individual pile resistances, shall be taken as the same as that for the uplift resistance of single piles as specified in Table 10.5.5.2.3-1.

The resistance factor for the uplift resistance of the pile group considered as a block shall be taken as specified in Table 10.5.5.2.3-1 for pile groups in all soils.

Figure 10.7.3.11-1—Uplift of Group of Closely Spaced Piles in Cohesionless Soils after Tomlinson (1987)

Figure 10.7.3.11-2—Uplift of Group of Piles in Cohesive Soils after Tomlinson (1987)

10.7.3.12—Nominal Lateral Resistance of Pile Foundations

The nominal resistance of pile foundations to lateral loads shall be evaluated based on both geomaterial and structural properties. The lateral soil resistance along the piles should be modeled using p - y curves developed for the soils at the site.

The applied loads shall be factored loads and they must include both lateral and axial loads. The analysis may be performed on a representative single pile with the appropriate pile top boundary condition or on the entire pile group. The p - y curves shall be modified for group effects. The p -multipliers in Table 10.7.2.4-1 should be used to modify the curves. If the pile cap will always be embedded, the p - y lateral resistance of the soil on the cap face may be included in the nominal lateral resistance.

The minimum penetration of the piles below ground (see Article 10.7.6) required in the contract should be established such that fixity is obtained. For this determination, the loads applied to the pile are factored as specified in Section 3, and a soil resistance factor of 1.0 shall be used as specified in Table 10.5.5.2.3-1.

If fixity cannot be obtained, additional piles should be added, larger diameter piles used if feasible to drive them to the required depth, or a wider spacing of piles in the group should be considered to provide the necessary lateral resistance. Batter piles may be added to provide the lateral resistance needed, unless downdrag is anticipated. If downdrag is anticipated, batter piles should not be used. The design procedure, if fixity cannot be obtained, should take into consideration the lack of fixity of the pile.

C10.7.3.12

Pile foundations are subjected to lateral loads due to wind, traffic loads, bridge curvature, stream flow, vessel or traffic impact and earthquake. Batter piles are sometimes used but they are somewhat more expensive than vertical piles and vertical piles are more effective against dynamic loads.

Additional details regarding methods of analysis using p - y curves, both for single piles and pile groups, are provided in Article 10.7.2.4. As an alternative to p - y analysis, strain wedge theory may be used (see Article 10.7.2.4).

When this analysis is performed, the loads are factored since the strength limit state is under consideration, but the resistances as represented by the p - y curves are not factored since they already represent the ultimate condition.

The strength limit state for lateral resistance is only structural (see Sections 5 and 6 for structural limit state design requirements), though the determination of pile fixity is the result of soil-structure interaction. A failure of the soil does not occur; the soil will continue to displace at constant or slightly increasing resistance. Failure occurs when the pile reaches the structural limit state, and this limit state is reached, in the general case, when the nominal combined bending and axial resistance is reached.

If the lateral resistance of the soil in front of the pile cap is included in the lateral resistance of the foundation, the effect of soil disturbance resulting from construction of the pile cap should be considered. In such cases, the passive resistance may need to be reduced to account for the effects of disturbance.

Lateral resistance of single piles may be determined by static load test. If a static lateral load test is to be performed, it shall follow the procedures specified in ASTM D3966.

10.7.3.13—Pile Structural Resistance

10.7.3.13.1—Steel Piles

The nominal axial compression resistance in the structural limit state for piles loaded in compression shall be as specified in Article 6.9.4.1 for noncomposite piles and Article 6.9.5.1 for composite piles. If the pile is fully embedded, λ in Eq. 6.9.5.1-1 shall be taken as zero.

The nominal axial resistance of horizontally unsupported noncomposite piles that extend above the ground surface in air or water shall be determined from Eqs. 6.9.4.1.1-1 or 6.9.4.1.1-2. The nominal axial resistance of horizontally unsupported composite piles that extend above the ground surface in air or water shall be determined from Eqs. 6.9.5.1-1 or 6.9.5.1-2.

The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

The resistance factors for the compression limit state are specified in Article 6.5.4.2.

10.7.3.13.2—Concrete Piles

The nominal axial compression resistance for concrete piles and prestressed concrete piles shall be as specified in Article 5.6.4.4.

The nominal axial compression resistance for concrete piles that are laterally unsupported in air or water shall be determined using the procedures given in Articles 5.6.4.3 and 4.5.3.2. The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

The resistance factor for the compression limit state for concrete piles shall be that given in Article 5.5.4.2 for concrete loaded in axial compression.

10.7.3.13.3—Timber Piles

The nominal axial compression resistance for timber piles shall be as specified in Article 8.8.2. The methods presented there include both laterally supported and laterally unsupported members.

The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

10.7.3.13.4—Buckling and Lateral Stability

In evaluating stability, the effective length of the pile shall be equal to the laterally unsupported length, plus an embedded depth to fixity.

For information on analysis and interpretation of load tests, see Article 10.7.2.4.

C10.7.3.13.1

Composite members refer to steel pipe piles that are filled with concrete.

The effective length given in Article C10.7.3.13.4 is an empirical approach to determining effective length. Computer methods are now available that can determine the axial resistance of a laterally unsupported compression member using a P - Δ analysis that includes a numerical representation of the lateral soil resistance (Williams et al., 2003). These methods are preferred over the empirical approach in Article C10.7.3.13.4.

C10.7.3.13.2

Article 5.6.4 includes specified limits on longitudinal reinforcement, spirals and ties. Methods are given for determining nominal axial compression resistance but they do not include the nominal axial compression resistance of prestressed members. Compression members are usually prestressed only where they are subjected to high levels of flexure. Therefore, a method of determining nominal axial compression resistance is not given.

Article 5.6.4.5 specifically permits an analysis based on equilibrium and strain compatibility. Methods are also available for performing a stability analysis (Williams et al., 2003).

C10.7.3.13.3

Article 8.5.2.3 requires that a reduction factor for long term loads of 0.75 be multiplied times the resistance factor for Strength Load Combination IV.

C10.7.3.13.4

For preliminary design, the depth to fixity below the ground, in ft, may be taken as:

that the scour resulting from the scour check flood and resistance factors consistent with Article 10.5.5.3.2 shall be used.

10.7.5—Corrosion and Deterioration

The effects of corrosion and deterioration from environmental conditions shall be considered in the selection of the pile type and in the determination of the required pile cross-section.

As a minimum, the following types of deterioration shall be considered:

- corrosion of steel pile foundations, particularly in fill soils, low-pH soils, and marine environments;
- sulfate, chloride, and acid attack of concrete pile foundations; and
- decay of timber piles from wetting and drying cycles or from insects or marine borers.

The following soil or site conditions should be considered as indicative of a potential pile deterioration or corrosion situation:

- resistivity less than 2,000 ohm-cm,
- pH less than 5.5,
- pH between 5.5 and 8.5 in soils with high organic content,
- sulfate concentrations greater than 1,000 ppm,
- landfills and cinder fills,
- soils subject to mine or industrial drainage,
- areas with a mixture of high resistivity soils and low resistivity high alkaline soils, and
- insects (wood piles).

The following water conditions should be considered as indicative of a potential pile deterioration or corrosion situation:

- chloride content greater than 500 ppm,
- sulfate concentration greater than 500 ppm,
- mine or industrial runoff,
- high organic content,
- pH less than 5.5,
- marine borers, and
- piles exposed to wet/dry cycles.

When chemical wastes are suspected, a full chemical analysis of soil and groundwater samples shall be considered.

C10.7.5

Resistivity, pH, chloride content, and sulfate concentration values have been adapted from those in Fang (1991) and Tomlinson (1987).

Some states use a coal tar epoxy paint system as a protective coating with good results.

The criterion for determining the potential for deterioration varies widely. An alternative set of recommendations is given by Elias (1990).

A field electrical resistivity survey or resistivity testing and pH testing of soil and groundwater samples may be used to evaluate the corrosion potential.

The deterioration potential of steel piles may be reduced by several methods, including protective coatings, concrete encasement, cathodic protection, use of special steel alloys, or increased steel area. Protective coatings should be resistant to abrasion and have a proven service record in the corrosive environment identified. Protective coatings should extend into noncorrosive soils a few feet because the lower portion of the coating is more susceptible to abrasion loss during installation.

Concrete encasement through the corrosive zone may also be used. The concrete mix should be of low permeability and placed properly. Steel piles protected by concrete encasement should be coated with a dielectric coating near the base of the concrete jacket.

The use of special steel alloys of nickel, copper, and potassium may also be used for increased corrosion resistance in the atmosphere or splash zone of marine piling.

Sacrificial steel area may also be used for corrosion resistance. This technique over sizes the steel section so that the available section after corrosion meets structural requirements.

Deterioration of concrete piles can be reduced by design procedures. These include use of a dense impermeable concrete, sulfate resisting Portland cement, increased steel cover, air-entrainment, reduced chloride content in the concrete mix, cathodic protection, and epoxy-coated reinforcement. Piles that are continuously submerged are less subject to deterioration. ACI 318, Section 4.5.2, provides maximum water-cement ratio requirements for special exposure conditions. ACI 318, Section 4.5.3, lists the appropriate types of cement for various types of sulfate exposure.

For prestressed concrete, ACI 318 recommends a maximum water-soluble chloride ion of 0.06 percent by weight of cement.

Cathodic protection of reinforcing and prestressing steel may be used to protect concrete from corrosion effects. This process induces electric flow from the anode to the cathode of the pile and reduces corrosion. An external DC power source may be required to drive the current. However, cathodic protection requires electrical

10.7.6—Determination of Minimum Pile Penetration

The minimum pile penetration, if required for the particular site conditions and loading, shall be based on the maximum depth (i.e., tip elevation) needed to meet the following requirements as applicable:

- single and pile group settlement (service limit state)
- lateral deflection (service limit state)
- uplift (strength limit state)
- penetration into bearing soils needed to get below soil causing drag loads on the pile foundation from static consolidation stresses on soft soil or drag loads due to liquefaction (strength and extreme event limit state, respectively)
- penetration into bearing soils needed to get below soil subject to scour
- penetration into bearing soils necessary to obtain fixity for resisting the applied lateral loads to the foundation (strength limit state)
- axial uplift, and nominal lateral resistance to resist extreme event limit state loads

The contract documents should indicate the minimum pile penetration, if applicable, as determined above only if one or more of the requirements listed above are applicable to the pile foundation. The contract documents should also include the required nominal axial compressive resistance, R_{ndr} as specified in Article 10.7.7 and the method by which this resistance will be verified, if applicable, such that the resistance factor(s) used for design are consistent with the construction field verification methods of nominal axial compressive pile resistance.

10.7.7—Determination of R_{ndr} Used to Establish Contract Driving Criteria for Nominal Bearing Resistance

The value of R_{ndr} used for the construction of the pile foundation to establish the driving criteria to obtain the nominal bearing resistance shall be the value that meets or exceeds the following limit states, as applicable:

- strength limit state nominal bearing resistance, specified in Article 10.7.3.8
- strength limit state nominal bearing resistance, accounting for scour specified in Article 10.7.3.6
- extreme event limit state nominal bearing resistance for seismic specified in Article 10.7.4

continuity between all steel and that necessitates bonding the steel for electric connection. This bonding is expensive and usually precludes the use of cathodic protection of concrete piles.

Epoxy coating of pile reinforcement has been found in some cases to be useful in resisting corrosion. It is important to ensure that the coating is continuous and free of holidays.

More detail on design for corrosion or other forms of deterioration is contained in Hannigan et al. (2006).

C10.7.6

A minimum pile penetration should only be specified if necessary to ensure that all of the applicable limit states are met. A minimum pile penetration should not be specified solely to meet axial compression resistance, i.e., bearing, unless field verification of the pile nominal bearing resistance is not performed as described in Article 10.7.3.8.

- extreme event limit state nominal bearing resistance considering scour, as specified in Article 10.7.4

10.7.8—Drivability Analysis

The establishment of the installation criteria for driven piles should include a drivability analysis. Except as specified herein, the drivability analysis shall be performed by the Engineer using a wave equation analysis, and the driving stresses, σ_{dr} , anywhere in the pile determined from the analysis shall be less than the following limits:

Steel piles, compression and tension:

$$\sigma_{dr} = 0.9\phi_{da}f_y \quad (10.7.8-1)$$

where:

f_y = specified minimum yield strength of steel (ksi)
 ϕ_{da} = resistance factor, as specified in Table 10.5.5.2.3-1

Concrete piles:

- In compression:

$$\sigma_{dr} = \phi_{da} 0.85f'_c \quad (10.7.8-2)$$

- In tension, considering only the steel reinforcement:

$$\sigma_{dr} = 0.7\phi_{da}f_y \quad (10.7.8-3)$$

where:

f'_c = compressive strength of the concrete (ksi)
 f_y = specified minimum yield strength of steel reinforcement (ksi)

Prestressed concrete piles, normal environments:

- In compression:

$$\sigma_{dr} = \phi_{da} (0.85f'_c - f_{pe}) \quad (10.7.8-4)$$

- In tension:

$$\sigma_{dr} = \phi_{da} (0.095\sqrt{f'_c} + f_{pe}) \quad (10.7.8-5)$$

where:

f_{pe} = effective prestressing stress in concrete (ksi)

Prestressed concrete piles, severe corrosive environments:

- In tension:

C10.7.8

Wave equation analyses should be conducted during design using a range of likely hammer/pile combinations, considering the soil and installation conditions at the foundation site. See Article 10.7.3.8.4 for additional considerations for conducting wave equation analyses. These analyses should be used to assess feasibility of the proposed foundation system and to establish installation criteria with regard to driving stresses to limit driving stresses to acceptable levels. For routine pile installation applications, e.g., smaller diameter, low nominal resistance piles, the development of installation criteria with regard to the limitation of driving stresses, e.g., minimum or maximum ram weight, hammer size, maximum acceptable driving resistance, etc., may be based on local experience, rather than conducting a detailed wave equation analysis that is project specific. Local experience could include previous drivability analysis results and actual pile driving experience that are applicable to the project specific situation at hand. Otherwise, a project specific drivability study should be conducted.

Drivability analyses may also be conducted as part of the project construction phase. When conducted during the construction phase, the drivability analysis shall be conducted using the contractor's proposed driving system. This information should be supplied by the contractor. This drivability analysis should be used to determine if the contractor's proposed driving system is capable of driving the pile to the maximum resistance anticipated without exceeding the factored structural resistance available, i.e., σ_{dr} .

$$\sigma_{dr} = \phi_{da} f_{pe} \quad (10.7.8-6)$$

Timber piles, in compression and tension:

$$\sigma_{dr} = \phi_{da} (2.6 F_{co}) \quad (10.7.8-7)$$

where:

F_{co} = base resistance of wood in compression parallel to the grain, as specified in Article 8.4.1.3 (ksi)

This drivability analysis shall be based on the maximum driving resistance needed:

- to obtain minimum penetration requirements, specified in Article 10.7.6,
- to overcome resistance of soil that cannot be counted upon to provide axial or lateral resistance throughout the design life of the structure, e.g., material subject to scour, or material subject to downdrag, and
- to obtain the required nominal bearing resistance.

In addition to this drivability analysis, the best approach to controlling driving stresses during pile installation is to conduct dynamic testing with signal matching to verify the accuracy of the wave equation analysis results. Note that if a drivability analysis is conducted using the wave equation for acceptance of the contractor's proposed driving system, but a different method is used to develop driving resistance, i.e., blow count, criterion to obtain the specified nominal pile resistance, e.g., a driving formula, the difference in the methods regarding the predicted driving resistance should be taken into account when evaluating the contractor's driving system. For example, the wave equation analysis could indicate that the contractor's hammer can achieve the desired bearing resistance, but the driving formula could indicate the driving resistance at the required nominal bearing is too high. Such differences should be considered when setting up the driving system acceptance requirements in the contract documents, though it is preferable to be consistent in the method used for acceptance of the contractor's driving system and the one used for developing driving criteria.

The selection of a blow count limit as a definition of refusal is difficult because it can depend on the site soil profile, the pile type, hammer performance, and possibly hammer manufacturer limitations to prevent hammer damage. In general, blow counts greater than 10–15 blows per inch should be used with care, particularly with concrete or timber piles. In cases where the driving is easy until near the end of driving, a higher blow count may sometimes be satisfactory, but if a high blow count is required over a large percentage of the depth, even ten blows per inch may be too large.

10.7.9—Probe Piles

Probe piles should be driven at several locations on the site to establish order length. If dynamic measurements are not taken, these probe piles should be driven after the driving criteria have been established.

If dynamic measurements during driving are taken, both order lengths and driving criteria should be established after the probe pile(s) are driven.

C10.7.9

Probe piles are sometimes known as test piles or indicator piles. It is common practice to drive probe piles at the beginning of the project (particularly with concrete piles) to establish pile order lengths and/or to evaluate site variability whether or not dynamic measurements are taken.

10.8—DRILLED SHAFTS

10.8.1—General

10.8.1.1—Scope

The provisions of this Section shall apply to the design of drilled shafts. Throughout these provisions, the use of the term “drilled shaft” shall be interpreted to mean a shaft constructed using either drilling (open hole or with drilling slurry) or casing plus excavation equipment and technology.

These provisions shall also apply to shafts that are constructed using casing advancers that twist or rotate

C10.8.1.1

Drilled shafts may be an economical alternative to spread footing or pile foundations, particularly when spread footings cannot be founded on suitable soil or rock strata within a reasonable depth or when driven piles are not viable. Drilled shafts may be an economical alternative to spread footings where scour depth is large. Drilled shafts may also be considered to resist high lateral or axial loads, or when deformation tolerances are small.

casings into the ground concurrent with excavation rather than drilling.

The provisions of this Section shall not be taken as applicable to drilled piles, e.g., augercast piles, installed with continuous flight augers that are concreted as the auger is being extracted.

10.8.1.2—Shaft Spacing, Clearance, and Embedment into Cap

If the center-to-center spacing of drilled shafts is less than 4.0 diameters, the interaction effects between adjacent shafts shall be evaluated. If the center-to-center spacing of drilled shafts is less than 6.0 diameters, the sequence of construction should be specified in the contract documents.

Shafts used in groups should be located such that the distance from the side of any shaft to the nearest edge of the cap is not less than 12.0 in. Shafts shall be embedded sufficiently into the cap to develop the required structural resistance.

10.8.1.3—Shaft Diameter and Enlarged Bases

If the shaft is to be manually inspected, the shaft diameter should not be less than 30.0 in. The diameter of columns supported by shafts should be smaller than or equal to the diameter of the drilled shaft.

In stiff cohesive soils, an enlarged base (bell, or underream) may be used at the shaft tip to increase the tip bearing area to reduce the unit end bearing pressure or to provide additional resistance to uplift loads.

For example, a movable bridge is a bridge where it is desirable to keep deformations small.

Drilled shafts are classified according to their primary mechanism for deriving load resistance either as floating (friction) shafts, i.e., shafts transferring load primarily by side resistance, or end-bearing shafts, i.e., shafts transferring load primarily by tip resistance.

It is recommended that the shaft design be reviewed for constructability prior to advertising the project for bids.

C10.8.1.2

Larger spacing may be required to preserve shaft excavation stability or to prevent communication between shafts during excavation and concrete placement.

Shaft spacing may be decreased if casing construction methods are required to maintain excavation stability and to prevent interaction between adjacent shafts.

C10.8.1.3

Nominal shaft diameters used for both geotechnical and structural design of shafts should be selected based on available diameter sizes.

If the shaft and the column are the same diameter, it should be recognized that the placement tolerance of drilled shafts is such that it will likely affect the column location. The shaft and column diameter should be determined based on the shaft placement tolerance, column and shaft reinforcing clearances, and the constructability of placing the column reinforcing in the shaft. A horizontal construction joint in the shaft at the bottom of the column reinforcing will facilitate constructability. Making allowance for the tolerance where the column connects with the superstructure, which could affect column alignment, can also accommodate this shaft construction tolerance.

In drilling rock sockets, it is common to use casing through the soil zone to temporarily support the soil to prevent cave-in, allow inspection and to produce a seal along the soil-rock contact to minimize infiltration of groundwater into the socket. Depending on the method of excavation, the diameter of the rock socket may need to be sized at least 6.0 in. smaller than the nominal casing size to permit seating of casing and insertion of rock drilling equipment.

Where practical, consideration should be given to extension of the shaft to a greater depth to avoid the difficulty and expense of excavation for enlarged bases.

- shaft bottom cleanout criteria;
- appropriate means to prevent side wall movement or failure (caving) such as temporary casing, slurry, or a combination of the two; and
- slurry maintenance requirements including minimum slurry head requirements, slurry testing requirements, and maximum time the shaft may be left open before concrete placement.

If for some reason one or more of these performance criteria are not met, the design should be reevaluated and the shaft repaired or replaced as necessary.

10.8.1.6—Determination of Shaft Loads

10.8.1.6.1—General

The factored loads to be used in shaft foundation design shall be as specified in Section 3. Computational assumptions that shall be used in determining individual shaft loads are also specified in Section 3.

C10.8.1.6.1

The specification and determination of top of cap loads is discussed extensively in Section 3. It should be noted that Article 3.6.2.1 states that dynamic load allowance need not be applied to foundation elements that are below the ground surface. Therefore, if shafts extend above the ground surface to act as columns the dynamic load allowance should be included in evaluating the structural resistance of that part of the shaft above the ground surface. The dynamic load allowance may be ignored in evaluating the geotechnical resistance.

10.8.1.6.2—Drag Load

The provisions of Articles 10.7.1.6.2 and 3.11.8 shall apply for determination of drag load. For shafts with tip bearing in a dense stratum or rock where design of the shaft is structurally controlled, drag load shall be considered at the structural strength and extreme event limit states. For shafts with tip bearing in soil, drag load shall be considered at the service, structural strength, and extreme event limit states.

C10.8.1.6.2

See Article C3.11.8.

Drag load may be estimated using the α -method, as specified in Article 10.8.3.5.1b. Shaft length assumed to not contribute to nominal side resistance should also be assumed to not contribute to drag load.

When using the α -method, an allowance should be made for a possible increase in the undrained shear strength as consolidation occurs. Drag load may also come from cohesionless soils above settling cohesive soils. The drag load caused by settling cohesionless soils may be estimated using the β method presented in Article 10.8.3.5.2.

Drag load occurs in response to relative downward deformation of the surrounding soil to that of the shaft, and may not exist if downward movement of the drilled shaft in response to axial compression load exceeds the vertical deformation of the soil. The response of a drilled shaft to drag load in combination with the other loads acting at the head of the shaft therefore is complex and a realistic evaluation of actual limit states that may occur requires careful consideration of two issues: (1) drilled shaft load-settlement behavior and (2) the time period over which drag load occurs relative to the time period over which nonpermanent components of load occur. When these factors are considered, it is appropriate to evaluate different drag loads at the structural strength, service, and extreme event limit states. These issues are addressed in Brown et al. (2010). Drag load is not present at the geotechnical strength limit state.

*10.8.1.6.3—Uplift**C10.8.1.6.3*

The provisions in Article 10.7.1.6.3 shall apply.

See Article C10.7.1.6.3.

10.8.2—Service Limit State Design**10.8.2.1—Tolerable Movements****C10.8.2.1**

The requirements of Article 10.5.2.1 shall apply.

See Article C10.5.2.1.

10.8.2.2—Settlement*10.8.2.2.1—General*

The settlement of a drilled shaft foundation involving either single-drilled shafts or groups of drilled shafts shall not exceed the movement criteria selected in accordance with Article 10.5.2.1.

*10.8.2.2.2—Settlement of Single-Drilled Shaft**C10.8.2.2.2*

The settlement of single-drilled shafts shall be estimated as a sum of the following:

- short-term settlement resulting from load transfer,
- consolidation settlement if constructed where cohesive soil exists beneath the shaft tip, and
- axial compression of the shaft.

The normalized load-settlement curves shown in Figures 10.8.2.2.2-1 through 10.8.2.2.2-4 should be used to limit the nominal shaft axial resistance computed as specified for the strength limit state in Article 10.8.3 for service limit state tolerable movements. Consistent values of normalized settlement shall be used for limiting the base and side resistance when using these Figures. Long-term settlement should be computed according to Article 10.7.2 using the equivalent footing method and added to the short-term settlements estimated using Figures 10.8.2.2.2-1 through 10.8.2.2.2-4.

O'Neill and Reese (1999) have summarized load-settlement data for drilled shafts in dimensionless form, as shown in Figures 10.8.2.2.2-1 through 10.8.2.2.2-4. These curves do not include consideration of long-term consolidation settlement for shafts in cohesive soils. Figures 10.8.2.2.2-1 and 10.8.2.2.2-2 show the load-settlement curves in side resistance and in end bearing for shafts in cohesive soils. Figures 10.8.2.2.2-3 and 10.8.2.2.2-4 are similar curves for shafts in cohesionless soils. These curves should be used for estimating short-term settlements of drilled shafts.

The Designer should exercise judgment relative to whether the trend line, one of the limits, or some relation in between should be used from Figures 10.8.2.2.2-1 through 10.8.2.2.2-4.

The values of the load-settlement curves in side resistance were obtained at different depths, taking into account elastic shortening of the shaft. Although elastic shortening may be small in relatively short shafts, it may be substantial in longer shafts. The amount of elastic shortening in drilled shafts varies with depth. O'Neill and Reese (1999) have described an approximate procedure for estimating the elastic shortening of long-drilled shafts.

Induced settlements for isolated drilled shafts are different for elements in cohesive soils and in cohesionless soils. In cohesive soils, the failure threshold, or nominal axial resistance corresponds to mobilization of the full available side resistance, plus the full available base resistance. In cohesive soils, the failure threshold has been shown to occur at an average normalized deformation of four percent of the shaft diameter. In cohesionless soils, the failure threshold is the force corresponding to mobilization of the full side resistance plus the base resistance, corresponding to settlement at a defined failure criterion. This has been traditionally defined as the bearing pressure required to cause vertical deformation equal to five percent of the shaft diameter, even though this does not correspond to complete failure of the soil beneath the base of the shaft.

Note that nominal base resistance in cohesionless soils is calculated according to the empirical correlation given by Eq. 10.8.3.5.2c-1 in terms of N -value. That relationship was developed using a base resistance corresponding to five percent normalized displacement. If a normalized displacement other than five percent is used, the base resistance calculated by Eq. 10.8.3.5.2c-1 must be corrected.

The curves in Figures 10.8.2.2.2-1 and 10.8.2.2.2-3 also show the settlements at which the side resistance is mobilized. The shaft skin friction, R_s , is typically fully mobilized at displacements of 0.2 percent to 0.8 percent of the shaft diameter for shafts in cohesive soils. For shafts in cohesionless soils, this value is 0.1 percent to 1.0 percent.

Figure 10.8.2.2.2-1 Normalized Load Transfer in Side Resistance versus Settlement in Cohesive Soils (from O'Neill and Reese, 1999)

Figure 10.8.2.2.2-2—Normalized Load Transfer in End Bearing versus Settlement in Cohesive Soils (from O'Neill and Reese, 1999)

Figure 10.8.2.2.2-3—Normalized Load Transfer in Side Resistance versus Settlement in Cohesionless Soils (from O'Neill and Reese, 1999)

The deflection-softening response typically applies to cemented or partially cemented soils, or other soils that exhibit brittle behavior, which have low residual shear strengths at larger deformations. Note that the trend line for sands is a reasonable approximation for either the deflection-softening or deflection-hardening response.

The normalized load-settlement curves require separate evaluation of an isolated drilled shaft for side and base resistance. Brown et al. (2010) provide alternate normalized load-settlement curves that may be used for estimation of settlement of a single drilled shaft considering combined side and base resistance. The method is based on modeling the average load deformation behavior observed from field load tests and incorporates the load test data used in development of the curves provided by O'Neill and Reese (1999). Additional methods that consider numerical simulations of axial load transfer and approximations based on elasto-plastic solutions are available in Brown et al. (2010).

Figure 10.8.2.2.2-4—Normalized Load Transfer in End Bearing versus Settlement in Cohesionless Soils (from O'Neill and Reese, 1999)

10.8.2.2.3—IGMs

For detailed settlement estimation of shafts in IGMs, the procedures described by Brown et al. (2010) should be used.

10.8.2.2.4—Group Settlement

The provisions of Article 10.7.2.3 shall apply. Shaft group effect shall be considered for groups of two shafts or more.

10.8.2.3—Horizontal Movement of Shafts and Shaft Groups

The provisions of Articles 10.5.2.1 and 10.7.2.4 shall apply.

For shafts socketed into rock, the input properties used to determine the response of the rock to lateral loading shall consider both the intact shear strength of the rock and the rock mass characteristics. The designer shall also consider the orientation and condition of discontinuities of the overall rock mass. Where specific adversely oriented discontinuities are not present but the rock mass is fractured such that its intact strength is considered compromised, the rock mass shear strength parameters should be assessed using the procedures for GSI rating in Article 10.4.6.4. For lateral deflection of the rock adjacent to the shaft greater than $0.0004b$, where b is

C10.8.2.2.3

IGMs are defined by Brown et al. (2010) as follows:

- *Cohesive IGM*—clay shales or mudstones with an S_u value of 5 to 50 ksf

C10.8.2.2.4

See Article C10.7.2.3.

O'Neill and Reese (1999) summarize various studies on the effects of shaft group behavior. These studies were for groups that consisted of 1×2 to 3×3 shafts. These studies suggest that group effects are relatively unimportant for shaft center-to-center spacing of $5D$ or greater.

C10.8.2.3

See Articles C10.5.2.1 and C10.7.2.4.

For shafts socketed into rock, approaches to developing p - y response of rock masses include both a weak rock response and a strong rock response. For the strong rock response, the potential for brittle fracture should be considered. If horizontal deflection of the rock mass is greater than $0.0004b$, a lateral load test to evaluate the response of the rock to lateral loading should be considered. Brown et al. (2010) provides a summary of a methodology that may be used to estimate the lateral load response of shafts in rock. Additional background on lateral loading of shafts in rock is provided in Turner (2006).

the diameter of the rock socket, the potential for brittle fracture of the rock shall be considered.

These methods for estimating the response of shafts in rock subjected to lateral loading use the unconfined compressive strength of the intact rock as the main input property. While this property is meaningful for intact rock, and was the key parameter used to correlate to shaft lateral load response in rock, it is not meaningful for fractured rock masses. If the rock mass is fractured enough to justify characterizing the rock shear strength using the GSI, the rock mass should be characterized as a c - ϕ material, and confining stress (i.e., σ'_3) present within the rock mass should be considered when establishing a rock mass shear strength for lateral response of the shaft. If the p - y method of analysis is used to model horizontal resistance, user-specified p - y curves should be derived. A method for developing hyperbolic p - y curves is described by Liang et al. (2009).

10.8.2.4—Downdrag

The provisions of Article 10.7.2.5 shall apply.

C10.8.2.4

See Article C10.7.2.5.

10.8.2.5—Lateral Squeeze

The provisions of Article 10.7.2.6 shall apply.

C10.8.2.5

See Article C10.7.2.6.

10.8.3—Strength Limit State Design

10.8.3.1—General

The nominal shaft resistances that shall be considered at the strength limit state include:

- axial compression resistance,
- axial uplift resistance,
- punching of shafts through strong soil into a weaker layer,
- lateral geotechnical resistance of soil and rock stratum,
- resistance when scour occurs, and
- structural resistance of shafts.

10.8.3.2—Groundwater Table and Buoyancy

The provisions of Article 10.7.3.5 shall apply.

C10.8.3.2

See Article C10.7.3.5.

10.8.3.3—Scour

The provisions of Article 10.7.3.6 shall apply.

C10.8.3.3

See Article C10.7.3.6.

10.8.3.4—Drag Load

The provisions of Article 10.7.3.7 shall apply.

C10.8.3.4

The static analysis procedures in Article 10.8.3.5 or an instrumented static load test may be used to estimate the available drilled shaft nominal side and tip resistances to withstand drag load plus other axial load effects.

As stated in Article C10.8.1.6.2, it is appropriate to apply different drag loads to evaluate different limit states. A drilled shaft with its tip bearing in stiff material,

such as rock or hard soil, would be expected to limit settlement to very small values. In this case, the full drag load could occur in combination with the other axial load effects because drag load will not be reduced if there is little or no downward movement of the shaft. Therefore, the factored load effects from all load components, including full factored drag load, should be used to check the structural strength limit state of the drilled shaft.

A rational approach to evaluating this strength limit state will incorporate the load effects occurring at this magnitude of downward displacement. This will include the factored axial load effects transmitted to the head of the shaft plus drag load occurring at a downward displacement defining the failure criterion. In many cases, this amount of downward displacement will reduce or eliminate drag load. For soil layers that undergo settlement exceeding the failure criterion (for example, five percent of B for shafts bearing in sand), drag load is likely to remain and should be included. This approach requires the designer to predict the magnitude of drag load occurring at a specified downward displacement. This can be accomplished using the hand calculation procedure described in Brown et al. (2010) or with commercially available software.

When drag load is determined to exist at a downward displacement defining failure, evaluation of drilled shafts for the geotechnical strength limit state in compression should be conducted under a load combination that is limited to permanent loads only, including the calculated drag load at a settlement defining the failure criterion but excluding nonpermanent loads, such as live load, temperature changes, etc. See Brown et al. (2010) for further discussion.

When analysis of a shaft subjected to drag load shows that the drag load would be eliminated to achieve a defined downward displacement, evaluation of geotechnical and structural strength limit states in compression should be conducted under the full-load combination corresponding to the relevant strength limit state, including the non-permanent components of load but not including drag load.

10.8.3.5—Nominal Axial Compression Resistance of Single Drilled Shafts

The factored resistance of drilled shafts, R_R , shall be taken as:

$$R_R = \phi R_n = \phi_{qp} R_p + \phi_{qs} R_s \quad (10.8.3.5-1)$$

in which:

$$R_p = q_p A_p \quad (10.8.3.5-2)$$

$$R_s = q_s A_s \quad (10.8.3.5-3)$$

C10.8.3.5

The nominal axial compression resistance of a shaft is derived from the tip resistance and/or shaft side resistance, i.e., skin friction. Both the tip and shaft resistances develop in response to foundation displacement. The maximum values of each are unlikely to occur at the same displacement, as described in Article 10.8.2.2.2.

For consistency in the interpretation of both static load tests (see Article 10.8.3.5.6) and the normalized curves of Article 10.8.2.2.2, it is customary to establish the failure criterion at the strength limit state at a gross deflection equal to five percent of the base diameter for drilled shafts.

where:

R_p	= nominal shaft tip resistance (kips)
R_s	= nominal shaft side resistance (kips)
ϕ_{ap}	= resistance factor for tip resistance, specified in Table 10.5.5.2.4-1
ϕ_{qs}	= resistance factor for shaft side resistance, specified in Table 10.5.5.2.4-1
q_p	= unit tip resistance (ksf)
q_s	= unit side resistance (ksf)
A_p	= area of shaft tip (ft ²)
A_s	= area of shaft side surface (ft ²)

The methods for estimating drilled shaft resistance provided in this Article should be used. Shaft strength limit state resistance methods not specifically addressed in this Article for which adequate successful regional or national experience is available may be used, provided adequate information and experience is also available to develop appropriate resistance factors.

10.8.3.5.1—Estimation of Drilled Shaft Resistance in Cohesive Soils

10.8.3.5.1a—General

Drilled shafts in cohesive soils should be designed by total and effective stress methods for undrained and drained loading conditions, respectively.

10.8.3.5.1b—Side Resistance

The nominal unit side resistance, q_s , in ksf, for shafts in cohesive soil loaded under undrained loading conditions by the α -Method shall be taken as:

$$q_s = \alpha S_u \quad (10.8.3.5.1b-1)$$

in which:

$$\alpha = 0.55 \text{ for } \frac{S_u}{p_a} \leq 1.5 \quad (10.8.3.5.1b-2)$$

$$\alpha = 0.55 - 0.1 \left(\frac{S_u}{p_a} - 1.5 \right) \text{ for } 1.5 \leq \frac{S_u}{p_a} \leq 2.5 \quad (10.8.3.5.1b-3)$$

where:

S_u = undrained shear strength (ksf)

O'Neill and Reese (1999) identify several methods for estimating the resistance of drilled shafts in cohesive and granular soils, intermediate geomaterials, and rock. The most commonly used methods are provided in this Article. Methods other than the ones provided in detail in this Article may be used provided that adequate local or national experience with the specific method is available to have confidence that the method can be used successfully and that appropriate resistance factors can be determined. At present, it must be recognized that these resistance factors have been developed using a combination of calibration by fitting to previous ASD practice and reliability theory (see Allen, 2005 for additional details on the development of resistance factors for drilled shafts). Such methods may be used as an alternative to the specific methodology provided in this Article, provided that:

- the method selected consistently has been used with success on a regional or national basis.
- significant experience is available to demonstrate that success.
- as a minimum, calibration by fitting to ASD is conducted to determine the appropriate resistance factor, if inadequate measured data are available to assess the alternative method using reliability theory. A similar approach as described by Allen (2005) should be used to select the resistance factor for the alternative method.

C10.8.3.5.1b

The α -method is based on total stress. For effective stress methods for shafts in clay, see Brown et al. (2010).

The adhesion factor is an empirical factor used to correlate the results of full-scale load tests with the material property or characteristic of the cohesive soil. The adhesion factor is usually related to S_u and is derived from the results of full-scale pile and drilled shaft, load tests. Use of this approach presumes that the measured value of S_u is correct and that all shaft behavior resulting from construction and loading can be lumped into a single parameter. Neither presumption is strictly correct, but the approach is used due to its simplicity.

Steel casing will generally reduce the side resistance of a shaft. No specific data for drilled shafts in clay are available regarding the reduction in skin friction resulting from the use of permanent casing relative to concrete placed directly against the soil

- α = adhesion factor (dim)
 p_a = atmospheric pressure (= 2.12 ksf)

The following portions of a drilled shaft, illustrated in Figure 10.8.3.5.1b-1, should not be taken to contribute to the development of resistance through skin friction:

- at least the top 5.0 ft of any shaft; and
- periphery of belled ends, if used.

When permanent casing is used, the side resistance shall be adjusted with consideration to the type and length of casing to be used, and how it is installed.

Values of α for contributing portions of shafts excavated dry in open or cased holes should be as specified in Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3.

when the casing is vibrated or rotated into the soil. Interface shear resistance for steel against clay can vary from 50 to 80 percent of the interface shear resistance for poured in place concrete against clay, depending on whether the steel is clean or rusty, respectively (Potyondy, 1961). A reduction factor applied to the calculated shaft side resistance of 0.6 to 0.75 is commonly used to account for the presence of permanent steel casing. Greater reduction in the side resistance may be necessary when installation methods result in reduced contact between the ground and the casing.

If open-ended pipe piles are driven full depth with an impact hammer before soil inside the pile is removed, and left as a permanent casing, driven pile static analysis methods may be used to estimate the side resistance as described in Article 10.7.3.8.6.

The upper 5.0 ft of the shaft is ignored in estimating R_n , to account for the effects of seasonal moisture changes, disturbance during construction, cyclic lateral loading, and low lateral stresses from freshly placed concrete.

Bells or underreams constructed in stiff fissured clay often settle sufficiently to result in the formation of a gap above the bell that will eventually be filled by slumping soil. Slumping will tend to loosen the soil immediately above the bell and decrease the side resistance along the lower portion of the shaft.

The value of α is often considered to vary as a function of S_u . Values of α for drilled shafts are recommended as shown in Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3, based on the results of back-analyzed, full-scale load tests. The load tests were conducted in insensitive cohesive soils. Therefore, if shafts are constructed in sensitive clays, values of α may be different than those obtained from Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3. Other values of α may be used if based on the results of load tests.

The depth of 5.0 ft at the top of the shaft may need to be increased if the drilled shaft is installed in expansive clay, if scour deeper than 5.0 ft is anticipated, if there is substantial groundline deflection from lateral loading, or if there are other long-term loads or construction factors that could affect shaft resistance.

The values of α obtained from Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3 are considered applicable for both compression and uplift loading.

Figure 10.8.3.5.1b-1—Explanation of Portions of Drilled Shafts Not Considered in Computing Side Resistance (Brown et al., 2010)

10.8.3.5.1c—Tip Resistance

For axially loaded shafts in cohesive soil, the nominal unit tip resistance, q_p , by the total stress method as provided in Brown et al. (2010) shall be taken as:

$$q_p = N_c S_u \leq 80.0 \text{ ksf} \quad (10.8.3.5.1c-1)$$

in which:

$$N_c = 6 \left[1 + 0.2 \left(\frac{Z}{D} \right) \right] \leq 9 \quad (10.8.3.5.1c-2)$$

where:

- D = diameter of drilled shaft (ft)
- Z = penetration of shaft (ft)
- S_u = undrained shear strength (ksf)

The value of S_u should be determined from the results of in-situ and/or laboratory testing of undisturbed samples obtained within a depth of 2.0 diameters below the tip of the shaft. If the soil within 2.0 diameters of the tip has $S_u < 0.50$ ksf, the value of N_c should be multiplied by 0.67.

10.8.3.5.2—Estimation of Drilled Shaft Resistance in Cohesionless Soils

10.8.3.5.2a—General

Shafts in cohesionless soils should be designed by effective stress methods for drained loading conditions or by empirical methods based on in-situ test results.

C10.8.3.5.1c

These equations are for total stress analysis. For effective stress methods for shafts in clay, see Brown et al. (2010).

The limiting value of 80.0 ksf for q_p is not a theoretical limit but a limit based on the largest measured values. A higher limiting value may be used if based on the results of a load test, or previous successful experience in similar soils.

C10.8.3.5.2a

The factored resistance should be determined in consideration of available experience with similar conditions.

The shear strength of cohesionless soils can be characterized by an angle of internal friction, ϕ , or empirically related to its SPT blow count, N . Methods

of estimating shaft resistance and end bearing are presented below. Judgment and experience should always be considered.

10.8.3.5.2b—Side Resistance

The side resistance for shafts in cohesionless soils shall be determined using the β method, take as:

$$q_s = \beta \sigma'_v \quad (10.8.3.5.2b-1)$$

in which:

$$\beta = (1 - \sin \phi'_f) \left(\frac{\sigma'_p}{\sigma'_v} \right)^{\sin \phi'_f} \tan \phi'_f \quad (10.8.3.5.2b-2)$$

where:

- β = load transfer coefficient (dim)
- ϕ'_f = friction angle of cohesionless soil layer ($^\circ$)
- σ'_p = effective vertical preconsolidation stress
- σ'_v = vertical effective stress at soil layer mid-depth

The correlation for effective soil friction angle for use in the above equations shall be taken as:

$$\phi'_f = 27.5 + 9.2 \log(N_{160}) \quad (10.8.3.5.2b-3)$$

where:

N_{160} = SPT N -value corrected for effective overburden stress

The preconsolidation stress in Eq. 10.8.3.5.2b-2 should be approximated through correlation to SPT N -values. For sands:

$$\frac{\sigma'_p}{p_a} = 0.47 (N_{60})^m \quad (10.8.3.5.2b-4)$$

where:

- m = 0.6 for clean quartzitic sands
- m = 0.8 for silty sand to sandy silts
- p_a = atmospheric pressure (same units as σ'_p : 2.12 ksf or 14.7 psi)

For gravelly soils:

$$\frac{\sigma'_p}{p_a} = 0.15 (N_{60}) \quad (10.8.3.5.2b-5)$$

When permanent casing is used, the side resistance shall be adjusted with consideration to the type and length of casing to be used, and how it is installed.

C10.8.3.5.2b

The method described herein is based on axial load tests on drilled shafts as presented by Chen and Kulhawy (2002) and updated by Kulhawy and Chen (2007). This method provides a rational approach for relating unit side resistance to N -values and to the state of effective stress acting at the soil-shaft interface. This approach replaces the previously used depth-dependent β -method developed by O'Neill and Reese (1999), which does not account for variations in N -value or effective stress on the calculated value of β . Further discussion, including the detailed development of Eq. 10.8.3.5.2b-2, is provided in (Brown et al., 2010).

Steel casing will generally reduce the side resistance of a shaft. No specific data for drilled shafts in cohesionless soil are available regarding the reduction in

10.8.3.5.4—Estimation of Drilled Shaft Resistance in Rock

10.8.3.5.4a—General

Drilled shafts in rock subject to compressive loading shall be designed to support factored loads in:

- side-wall shear comprising skin friction on the wall of the rock socket; or
- end bearing on the material below the tip of the drilled shaft; or
- a combination of both.

The difference in the deformation required to mobilize skin friction in soil and rock versus what is required to mobilize end bearing shall be considered when estimating axial compressive resistance of shafts embedded in rock. Where end bearing in rock is used as part of the axial compressive resistance in the design, the contribution of skin friction in the rock shall be reduced to account for the loss of skin friction that occurs once the shear deformation along the shaft sides is greater than the peak rock shear deformation, i.e., once the rock shear strength begins to drop to a residual value.

C10.8.3.5.4a

Methods presented in this Article to calculate drilled shaft axial resistance require an estimate of the uniaxial compressive strength of rock core. Unless the rock is massive, the strength of the rock mass is most frequently controlled by the discontinuities, including orientation, length, and roughness, and the behavior of the material that may be present within the discontinuity, e.g., gouge or infilling. The methods presented are semi-empirical and are based on load test data and site-specific correlations between measured resistance and rock core strength.

Design based on side-wall shear alone should be considered for cases in which the base of the drilled hole cannot be cleaned and inspected or where it is determined that large movements of the shaft would be required to mobilize resistance in end bearing.

Design based on end-bearing alone should be considered where sound bedrock underlies low strength overburden materials, including highly weathered rock. In these cases, however, it may still be necessary to socket the shaft into rock to provide lateral stability.

Where the shaft is drilled some depth into sound rock, a combination of sidewall shear and end bearing can be assumed (Kulhawy and Goodman, 1980).

If the rock is degradable, use of special construction procedures, larger socket dimensions, or reduced socket resistance should be considered.

Factors that should be considered when making an engineering judgment to neglect any component of resistance (side or base) are discussed in Article 10.8.3.5.4d. In most cases, both side and base resistances should be included in limit state evaluation of rock-socketed shafts.

For drilled shafts installed in karstic formations, exploratory borings should be advanced at each drilled shaft location to identify potential cavities. Layers of compressible weak rock along the length of a rock socket and within approximately three socket diameters or more below the base of a drilled shaft may reduce the resistance of the shaft.

For rock that is stronger than concrete, the concrete shear strength will control the available side friction, and the strong rock will have a higher stiffness, allowing significant end bearing to be mobilized before the side wall shear strength reaches its peak value. Note that concrete typically reaches its peak shear strength at about 250 to 400 microstrain (for a 10-ft long rock socket, this is approximately 0.5 in. of deformation at the top of the rock socket). If strains or deformations greater than the value at the peak shear stress are anticipated to mobilize the desired end bearing in the rock, a residual value for the skin friction can still be used. Article 10.8.3.5.4d provides procedures for computing a residual value

10.8.3.5.4b—Side Resistance

For drilled shafts socketed into rock, unit side resistance, q_s in ksf, shall be taken as (Kulhawy et al., 2005):

$$\frac{q_s}{p_a} = C \sqrt{\frac{q_u}{p_a}} \quad (10.8.3.5.4b-1)$$

where:

- p_a = atmospheric pressure taken as 2.12 ksf
 C = regression coefficient taken as 1.0 for normal conditions
 q_u = uniaxial compressive strength of rock (ksf)

If the uniaxial compressive strength of rock forming the sidewall of the socket exceeds the drilled shaft concrete compressive strength, the value of concrete compressive strength, f'_c , shall be substituted for q_u in Eq. 10.8.3.5.4b-1.

For fractured rock that caves and cannot be drilled without some type of artificial support, the unit side resistance shall be taken as:

$$\frac{q_s}{p_a} = 0.65 \alpha_E \sqrt{\frac{q_u}{p_a}} \quad (10.8.3.5.4b-2)$$

The joint modification factor, α_E is given in Table 10.8.3.5.4b-1 based on RQD and visual inspection of joint surfaces.

Table 10.8.3.5.4b-1—Estimation of α_E (O'Neill and Reese, 1999)

RQD (%)	Joint Modification Factor, α_E	
	Closed Joints	Open or Gouge-Filled Joints
100	1.00	0.85
70	0.85	0.55
50	0.60	0.55
30	0.50	0.50
20	0.45	0.45

of the skin friction based on the properties of the rock and shaft.

C10.8.3.5.4b

Eq. 10.8.3.5.4b-1 is based on regression analysis of load test data as reported by Kulhawy et al. (2005) and includes data from previous studies by Horvath and Kenney (1979), Rowe and Armitage (1987), Kulhawy and Phoon (1993), and others. The recommended value of the regression coefficient $C = 1.0$ is applicable to normal rock sockets, defined as sockets constructed with conventional equipment and resulting in nominally clean sidewalls without resorting to special procedures or artificial roughening. Rock that is prone to smearing or rapid deterioration upon exposure to atmospheric conditions, water, or slurry are outside the normal range and may require additional measures to insure reliable side resistance. Rocks exhibiting this type of behavior include clay shales and other argillaceous rocks. Rock that cannot support construction of an unsupported socket without caving is also outside the normal and will likely exhibit lower side resistance than given by Eq. 10.8.3.5.4b-1 with $C = 1.0$. For additional guidance on assessing the magnitude of C , see Brown et al. (2010).

Shafts are sometimes constructed by supporting the hole with temporary casing or by grouting the rock ahead of the excavation. When using these construction methods, disturbance of the sidewall results in lower unit side resistances. Based on O'Neill and Reese (1999) and as discussed in Brown et al. (2010), the reduction in side resistance can be related empirically to the RQD and joint conditions.

10.8.3.5.4c—Tip Resistance

End-bearing for drilled shafts in rock may be taken as follows:

- If the rock below the base of the drilled shaft to a depth of $2.0B$ is either intact or tightly jointed, i.e., no compressible material or gouge-filled seams, and the depth of the socket is greater than $1.5B$:

$$q_p = 2.5q_u \quad (10.8.3.5.4c-1)$$

- If the rock below the base of the shaft to a depth of $2.0B$ is jointed, the joints have random orientation, and the condition of the joints can be evaluated as:

$$q_p = A + q_u \left[m_b \left(\frac{A}{q_u} \right) + s \right]^a \quad (10.8.3.5.4c-2)$$

In which:

$$A = \sigma'_{vb} + q_u \left[m_b \left(\frac{\sigma'_{v,b}}{q_u} \right) + s \right]^a \quad (10.8.3.5.4c-3)$$

where:

σ'_{vb} = vertical effective stress at the socket bearing elevation (tip elevation)

s , a , and m_b = Hoek–Brown strength parameters for the fractured rock mass determined from GSI (see Article 10.4.6.4)

q_u = uniaxial compressive strength of intact rock

Eq. 10.8.3.5.4c-1 should be used as an upper-bound limit to base resistance calculated by Eq. 10.8.2.5.4c-2, unless local experience or load tests can be used to validate higher values.

10.8.3.5.4d—Combined Side and Tip Resistance

Design methods that consider the difference in shaft movement required to mobilize skin friction in rock versus what is required to mobilize end bearing shall be used to estimate axial compressive resistance of shafts embedded in rock.

C10.8.3.5.4c

If end bearing in the rock is to be relied upon, and wet construction methods are used, bottom clean-out procedures such as airlifts should be specified to ensure removal of loose material before concrete placement.

The use of Eq. 10.8.3.5.4c-1 also requires that there are no solution cavities or voids below the base of the drilled shaft.

For further information, see Brown et al. (2010).

Bearing capacity theory provides a framework for evaluation of base resistance for cases where the bearing rock can be characterized by its GSI. Eq. 10.8.3.5.4c-2 (Turner and Ramey, 2010) is a lower bound solution for bearing resistance of a drilled shaft bearing on or socketed into a fractured rock mass. Fractured rock describes a rock mass intersected by multiple sets of intersecting joints such that the strength is controlled by the overall mass response and not by failure along pre-existing structural discontinuities. This generally applies to rock that can be characterized by the descriptive terms shown in Figure 10.4.6.4-1 (e.g., blocky, disintegrated).

C10.8.3.5.4d

A design decision to be addressed when using rock sockets is whether to neglect one or the other component of resistance (side or base). For example, design based on side resistance alone is sometimes assumed for cases in which the base of the drilled hole cannot be cleaned and inspected or where it is determined that large downward movement of the shaft would be required to mobilize tip resistance. However, before making a decision to omit tip resistance, careful consideration should be given to applying available methods of quality construction and inspection that can provide confidence in tip resistance. Quality construction practices can result in adequate clean-out at the base of rock sockets, including those constructed by wet methods. In many cases, the cost of quality control and assurance is offset by the economies

achieved in socket design by including tip resistance. Load testing provides a means to verify tip resistance in rock.

Reasons cited for neglecting side resistance of rock sockets include:

- (1) the possibility of strain-softening behavior of the sidewall interface,
- (2) the possibility of degradation of material at the borehole wall in argillaceous rocks, and
- (3) uncertainty regarding the roughness of the sidewall.

Brittle behavior along the sidewall, in which side resistance exhibits a significant decrease beyond its peak value, is not commonly observed in load tests on rock sockets. If there is reason to believe strain softening will occur, laboratory direct shear tests of the rock-concrete interface can be used to evaluate the load-deformation behavior and account for it in design. These cases would also be strong candidates for conducting field load tests. Investigating the sidewall shear behavior through laboratory or field testing is generally more cost-effective than neglecting side resistance in the design. Application of quality control and assurance through inspection is also necessary to confirm that sidewall conditions in production shafts are of the same quality as laboratory or field test conditions.

Materials that are prone to degradation at the exposed surface of the borehole and are prone to a “smooth” sidewall generally are argillaceous sedimentary rocks such as shale, claystone, and siltstone. Degradation occurs due to expansion, opening of cracks and fissures combined with groundwater seepage, and by exposure to air and/or water used for drilling. Hassan and O’Neill (1997) note that this behavior is most prevalent in cohesive IGMs and that in the most severe cases degradation results in a smear zone at the interface. Smearing may reduce load transfer significantly. As reported by Abu-Hejleh et al. (2003), both smearing and smooth sidewall conditions can be prevented in cohesive IGMs by using roughening tools during the final pass with the rock auger or by grooving tools. Careful inspection prior to concrete placement is required to confirm roughness of the sidewalls. Only when these measures cannot be confirmed would there be cause for neglecting side resistance in design.

Analytical tools for evaluating the load transfer behavior of rock socketed shafts are given in Turner (2006) and Brown et al. (2010).

10.8.3.5.5—Estimation of Drilled Shaft Resistance in IGMs

For detailed base and side resistance estimation procedures for shafts in cohesive IGMs, the procedures provided by Brown et al. (2010) should be used.

C10.8.3.5.5

See Article 10.8.2.2.3 for a definition of an IGM.

10.8.3.5.6—Shaft Load Test

When used, load tests shall be conducted in representative soil conditions using shafts constructed in a manner and of dimensions and materials similar to those planned for the production shafts. The load test shall follow the procedures specified in ASTM D1143. The loading procedure should follow the Quick Load Test Method, unless detailed longer-term load-settlement data is needed, in which case the standard loading procedure should be used.

The nominal resistance shall be determined according to the failure definition of either:

- “plunging” of the drilled shaft, or
- a gross settlement or uplift of five percent of the diameter of the shaft if plunging does not occur.

The resistance factors for axial compressive resistance or axial uplift resistance shall be taken as specified in Table 10.5.5.2.4-1.

Regarding the use of shaft load test data to determine shaft resistance, the load test results should be applied to production shafts that are not load tested by matching the static resistance prediction to the load test results. The calibrated static analysis method should then be applied to adjacent locations within the site to determine the shaft tip elevation required, in consideration of variations in the geologic stratigraphy and design properties at each production shaft location. The definition of a site and number of load tests required to account for site variability shall be as specified in Article 10.5.5.2.3.

C10.8.3.5.6

For a larger project where many shafts are to be used, it may be cost-effective to perform a full-scale load test on a drilled shaft during the design phase of a project to confirm response to load.

Load tests should be conducted following prescribed written procedures that have been developed from accepted standards and modified, as appropriate, for the conditions at the site. The Quick Test Procedure is desirable because it avoids problems that frequently arise when performing a static test that cannot be started and completed within an eight-hour period. Tests that extend over a longer period are difficult to perform due to the limited number of experienced personnel that are usually available. The Quick Test has proven to be easily performed in the field, and the results usually are satisfactory. However, if the formation in which the shaft is installed may be subject to significant creep settlement, alternative procedures provided in ASTM D1143 should be considered.

Load tests are conducted on full-scale drilled shaft foundations to provide data regarding nominal axial resistance, load-displacement response, and shaft performance under the design loads, and to permit assessment of the validity of the design assumptions for the soil conditions at the test shaft(s).

Tests can be conducted for compression, uplift, lateral loading, or for combinations of loading. Full-scale load tests in the field provide data that include the effects of soil, rock, and groundwater conditions at the site; the dimensions of the shaft; and the procedures used to construct the shaft.

The results of full-scale load tests can differ even for apparently similar ground conditions. Therefore, care should be exercised in generalizing and extrapolating the test results to other locations.

For large diameter shafts, where conventional reaction frames become unmanageably large, load testing using Osterberg load cells may be considered. Additional discussion regarding load tests is provided in O'Neill and Reese (1999). Alternatively, smaller diameter shafts may be load tested to represent the larger diameter shafts (but no less than one-half the full scale production shaft diameter), provided that appropriate measures are taken to account for potential scale effects when extrapolating the results to the full scale production shafts.

Plunging occurs when a steady increase in movement results from incrementally small increases in load, e.g., 2.0 kips.

10.8.3.6—Shaft Group Resistance*10.8.3.6.1—General*

Reduction in resistance from group effects shall be evaluated.

C10.8.3.6.1

If casing is advanced in front of the excavation heading, this reduction need not be made.

10.8.3.6.2—Cohesive Soil

The provisions of Article 10.7.3.9 shall apply.

The resistance factor for the group resistance of an equivalent pier or block failure provided in Table 10.5.5.2.4-1 shall apply where the cap is, or is not, in contact with the ground.

The resistance factors for the group resistance calculated using the sum of the individual drilled shaft resistances are the same as those for the single-drilled shaft resistances.

10.8.3.6.3—Cohesionless Soil

The individual nominal resistance of each shaft in a group should be reduced by applying an adjustment factor, η , taken as shown in Table 10.8.3.6.3-1.

For intermediate spacings, the value of η may be determined by linear interpolation.

C10.8.3.6.2

The efficiency of groups of drilled shafts in cohesive soil may be less than that of the individual shaft due to the overlapping zones of shear deformation in the soil surrounding the shafts.

C10.8.3.6.3

The bearing resistance of drilled shaft groups in sand is less than the sum of the individual shafts due to overlap of shear zones in the soil between adjacent shafts and loosening of the soil during construction. The recommended reduction factors are based in part on theoretical considerations and on limited load test results. See O'Neill and Reese (1999) for additional details and a summary of group load test results. It should be noted that most of the available group load test results were obtained for sands above the water table and for relatively small groups, e.g., groups of 3–9 shafts. For larger shaft groups or for shaft groups of any size below the water table, more conservative values of η should be considered.

These reduction factors presume that good shaft installation practices are used to minimize or eliminate the relaxation of the soil between shafts and caving. If this cannot be adequately controlled due to difficult soil conditions or for other reasons, lower group reduction factors should be considered, or steps should be taken during and after shaft construction to restore the soil to its original condition.

Table 10.8.3.6.3-1—Group Reduction Factors for Bearing Resistance of Shafts in Sand

Shaft Group Configuration	Shaft Center-to-Center Spacing	Special Conditions	Reduction Factor for Group Effects, η
Single Row	2D		0.90
	3D or more		1.0
Multiple Row	2.5D		0.67
	3D		0.80
	4D or more		1.0
Single and Multiple Rows	2D or more	Shaft group cap in intimate contact with ground consisting of medium dense or denser soil, and no scour below the shaft cap is anticipated	1.0
Single and Multiple Rows	2D or more	Pressure grouting is used along the shaft sides to restore lateral stress losses caused by shaft installation, and the shaft tip is pressure grouted	1.0

10.8.3.6.4—Shaft Groups in Strong Soil Overlying Weak Soil

For shaft groups that are collectively tipped within a strong soil layer overlying a soft, cohesive layer, block bearing resistance shall be evaluated in accordance with Article 10.7.3.9.

10.8.3.7—Uplift Resistance

10.8.3.7.1—General

Uplift resistance shall be evaluated when upward loads act on the drilled shafts. Drilled shafts subjected to uplift forces shall be investigated for resistance to pullout, for their structural strength, and for the strength of their connection to supported components.

10.8.3.7.2—Uplift Resistance of Single Drilled Shaft

The uplift resistance of a single straight-sided drilled shaft should be estimated in a manner similar to that for determining side resistance for drilled shafts in compression, as specified in Article 10.8.3.5.

In determining the uplift resistance of a belled shaft, the side resistance above the bell should conservatively be neglected if the resistance of the bell is considered, and it can be assumed that the bell behaves as an anchor.

The factored nominal uplift resistance of a belled drilled shaft in a cohesive soil, R_R , in kips, should be determined as:

$$R_R = \phi R_n = \phi_{up} R_{shell} \quad (10.8.3.7.2-1)$$

in which:

$$R_{shell} = q_{shell} A_u \quad (10.8.3.7.2-2)$$

where:

- q_{shell} = $N_u S_u$ (ksf)
- A_u = $\pi(D_p^2 - D^2)/4$ (ft²)
- N_u = uplift adhesion factor (dim)
- D_p = diameter of the bell (ft)
- D_b = depth of embedment in the founding layer (ft)
- D = shaft diameter (ft)
- S_u = undrained shear strength averaged over a distance of 2.0 bell diameters ($2D_p$) above the base (ksf)
- ϕ_{up} = resistance factor, specified in Table 10.5.5.2.4-1

If the soil above the founding stratum is expansive, S_u should be averaged over the lesser of either $2.0D_p$ above the bottom of the base or over the depth of penetration of the drilled shaft in the founding stratum.

C10.8.3.7.2

The resistance factors for uplift are lower than those for axial compression. One reason for this is that drilled shafts in tension unload the soil, thus reducing the overburden effective stress and hence the uplift side resistance of the drilled shaft. Empirical justification for uplift resistance factors is provided in Article C10.5.5.2.3 and in Allen (2005).

Figure C10.8.3.7.2-1—Uplift of a Belled Drilled Shaft

The value of N_u may be assumed to vary linearly from 0.0 at $D_b/D_p = 0.75$ to a value of 8.0 at $D_b/D_p = 2.5$, where D_b is the depth below the founding stratum. The top of the founding stratum should be taken at the base of zone of seasonal moisture change.

10.8.3.7.3—Group Uplift Resistance

The provisions of Article 10.7.3.11 shall apply.

10.8.3.7.4—Uplift Load Test

The provisions of Article 10.7.3.10 shall apply.

10.8.3.8—Nominal Horizontal Resistance of Shaft and Shaft Groups

The provisions of Article 10.7.3.12 apply.

The design of horizontally loaded drilled shafts shall account for the effects of interaction between the shaft and ground, including the number of shafts in the group.

For shafts used in groups, the drilled shaft head shall be fixed into the cap.

10.8.3.9—Shaft Structural Resistance

10.8.3.9.1—General

The structural design of drilled shafts shall be in accordance with the provisions of Section 5 for the design of reinforced concrete.

10.8.3.9.2—Buckling and Lateral Stability

The provisions of Article 10.7.3.13.4 shall apply.

10.8.3.9.3—Reinforcement

Where the potential for lateral loading is insignificant, drilled shafts may be reinforced for axial loads only. Those portions of drilled shafts that are not supported laterally shall be designed as reinforced concrete columns in accordance with Article 5.6.4. Reinforcing steel shall extend a minimum of 10.0 ft below the plane where the soil provides fixity.

Where the potential for lateral loading is significant, the unsupported portion of the shaft shall be designed in accordance with Article 5.11.

The minimum spacing between longitudinal bars, as well as between transverse reinforcement bars, shall be sufficient to allow free passage of the concrete through the cage and into the annulus between the cage and the borehole wall.

The assumed variation of N_u is based on Yazdanbod et al. (1987).

This method does not include the uplift resistance contribution due to soil suction and the weight of the shaft.

C10.8.3.7.4

See Article C10.7.3.10.

C10.8.3.8

See Article C10.7.3.12.

C10.8.3.9.2

See Article C10.7.3.13.4.

C10.8.3.9.3

Shafts constructed using generally accepted procedures are not normally stressed to levels such that the allowable concrete stress is exceeded. Exceptions include:

- Shafts with sockets in hard rock,
- Shafts subjected to lateral loads,
- Shafts subjected to uplift loads from expansive soils or direct application of uplift loads, and
- Shafts with unreinforced bells.

Maintenance of the spacing of reinforcement and the maximum aggregate size requirements are important to ensure that the high-slump concrete mixes normally used for drilled shafts can flow readily between the steel bars during concrete placement. See Article 5.12.9.5.2 for specifications regarding the minimum clear spacing required between reinforcing cage bars.

A shaft can be considered laterally supported:

- below the zone of liquefaction or seismic loads,

- in rock, or
- 5.0 ft below the ground surface or the lowest anticipated scour elevation.

“Laterally supported” does not mean “fixed.” Fixity would occur somewhat below this location and depends on the stiffness of the supporting soil.

The out-to-out dimension of the assembled reinforcing cage should be sufficiently smaller than the diameter of the drilled hole to ensure free flow of concrete around the reinforcing as the concrete is placed. See Article 5.12.9.

See Article C10.7.5 regarding assessment of corrosivity. In addition, consideration should be given to the ability of the concrete and steel shell to bond together.

The minimum requirements to consider the steel shell to be load carrying shall be as specified in Article 5.12.9.5.2.

10.8.3.9.4—Transverse Reinforcement

Transverse reinforcement may be constructed of hoops or spirals.

Seismic provisions shall be in accordance with Article 5.11.

10.8.3.9.5—Concrete

The maximum aggregate size, slump, wet or dry placement, and necessary design strength should be considered when specifying shaft concrete. The concrete selected should be capable of being placed and adequately consolidated for the anticipated construction condition, and shaft details should be specified. The maximum size aggregate shall meet the requirements of Article 10.8.3.9.3.

C10.8.3.9.5

When concrete is placed in shafts, vibration is often not possible except for the uppermost cross-section. Vibration should not be used for high slump concrete.

10.8.3.9.6—Reinforcement into Superstructure

Sufficient reinforcement shall be provided at the junction of the shaft with the shaft cap or column to make a suitable connection. The embedment of the reinforcement into the cap shall comply with the provision for cast-in-place piles in Section 5.

10.8.3.9.7—Enlarged Bases

Enlarged bases shall be designed to ensure that the plain concrete is not overstressed. The enlarged base shall slope at a side angle not greater than 30 degrees from the vertical and have a bottom diameter not greater than three times the diameter of the shaft. The thickness of the bottom edge of the enlarged base shall not be less than 6.0 in.

10.8.4—Extreme Event Limit State

The provisions of Article 10.5.5.3 and 10.7.4 shall apply.

C10.8.4

See Articles C10.5.5.3 and C10.7.4.

10.9—MICROPILES

10.9.1—General

The provisions of Article 10.7.1 shall apply, except as noted herein.

Micropiles shall be classified by type based on their method of installation as follows:

- Type A micropiles are constructed by placing a sand-cement mortar or neat cement grout in the pile under a gravity head only;
- Type B micropiles are constructed by injecting a neat cement grout under pressure (typically 6–21 ksf) into the drilled hole while the temporary drill casing or auger is withdrawn;
- Type C micropiles are grouted as for Type A, followed 15–25 min after primary grouting by injection of additional grout under pressure (typically greater than 21 ksf) via a preplaced sleeved grout pipe.
- Type D micropiles are grouted similar to Type C, but the primary grout is allowed to harden before injecting the secondary grout under pressure (typically 42–170 ksf) with a packer to achieve treatment of specific pile intervals or material horizons; or
- Type E micropiles are constructed by drilling with grout injection through a continuous-thread, hollow-core steel bar. The grout injection serves to flush cuttings, achieve grout penetration into the ground and stabilize the drill hole. Often the initial grout has a high water to cement ratio and is then replaced with a thicker structural grout near the completion of drilling.

Primary grout, where it provides direct load transfer along the micropile to the surrounding ground, shall be Portland cement-based grout injected into the micropile hole before or after reinforcement installation.

Post grouting, also known as regrouting or secondary grouting, shall be taken as the injection of additional Portland cement grout into the bond length of the micropile after set up of primary grout to enhance the grout–ground bond.

10.9.1.1—Scope

The provisions of this Article shall apply to the design of micropiles.

The provisions of this section shall not be taken as applicable to drilled piles, e.g., augercast piles, installed with continuous flight augers that are concreted as the auger is being extracted.

C10.9.1

Micropiles should be considered:

- where footings cannot be founded on rock, stiff cohesive, or granular foundation material at a reasonable expense;
- where soil conditions would normally permit the use of spread footings, but the potential for erosion exists;
- where pile foundations must penetrate rock;
- where difficult subsurface conditions (e.g., cobbles, boulders, debris fill, running sands) would hinder installation of driven piles or drilled shafts;
- where difficult access or limited headroom preclude use of other deep foundation systems;
- where foundations must bridge over or penetrate subsurface voids;
- where vibration limits preclude conventional pile driving operations or access by drilled shaft rigs; or
- when underpinning or retrofitting existing foundations.

A typical detail for a composite reinforced micropile is illustrated in Figure C10.9.1-1.

Figure C10.9.1-1—Typical Detail of Composite Reinforced Micropile (after Sabatini et al., 2005)

10.9.1.2—Minimum Micropile Spacing, Clearance, and Embedment into Cap

Center-to-center pile spacing should not be less than 30.0 in. or 3.0 pile diameters, whichever is greater. Otherwise, the provisions of Article 10.7.1.2 shall apply.

10.9.1.3—Micropiles through Embankment Fill

Micropiles extending through embankments shall penetrate a minimum of 10.0 ft into original ground, unless the required nominal axial and lateral resistance occurs at a lesser penetration below the embankment within bedrock or other suitable support materials.

10.9.1.4—Battered Micropiles

The provisions of Article 10.7.1.4 shall apply.

10.9.1.5—Micropile Design Requirements

Micropile design shall address the following issues as appropriate:

- nominal axial resistance to be specified in the contract and size of micropile group required to provide adequate support, with consideration of how nominal axial micropile resistance will be determined in the field;
- group interaction;
- pile quantity estimation from estimated pile penetration required to meet nominal axial resistance and other design requirements;
- minimum pile penetration necessary to satisfy the requirements caused by uplift, scour, drag load, settlement, liquefaction, lateral loads, and seismic conditions;
- foundation deflection to meet the established movement and associated structure performance criteria;
- pile foundation nominal structural resistance; and
- long-term durability of the micropile in service, i.e., corrosion and deterioration.

10.9.1.6—Determination of Micropile Loads

The provisions of Article 10.7.1.6 shall apply.

10.9.1.6.1—Drag Load

The provisions of Articles 10.7.1.6.2 and 3.11.8 shall apply.

10.9.1.6.2—Uplift Due to Expansive Soils

The provisions in Article 10.7.1.6.3 shall apply.

C10.9.1.3

If compressible soils are located beneath the embankment, micropiles should be installed after embankment settlement is complete, if possible, to minimize or eliminate drag load.

C10.9.1.4

See Article C10.7.1.4.

C10.9.1.5

The micropile design process is discussed in detail in *Micropile Design and Construction* (Sabatini et al., 2005).

10.9.2.2—Tolerable Movements**C10.9.2.2**

The provisions of Articles 10.5.2.1 and 10.5.2.2 shall apply.

See Articles C10.5.2.1 and C10.5.2.2.

10.9.2.3—Settlement**C10.9.2.3**

The provisions of Article 10.7.2.3 shall apply.

See Article C10.7.2.3.
Methods for calculating the settlement of micropiles are discussed in Sabatini et al. (2005).

*10.9.2.3.1—Micropile Groups in Cohesive Soil**C10.9.2.3.1*

The provisions of Article 10.7.2.3.1 shall apply.

See Article 10.7.2.3.1.

*10.9.2.3.2—Micropile Groups in Cohesionless Soil**C10.9.2.3.2*

The provisions of Article 10.7.2.3.2 shall apply.

See Article C10.7.2.3.2.

10.9.2.4—Horizontal Micropile Foundation Movement**C10.9.2.4**

The provisions of Articles 10.5.2.1 and 10.7.2.4 shall apply.

See Articles C10.5.2.1 and C10.7.2.4.

10.9.2.5—Downdrag**C10.9.2.5**

The provisions of Article 10.7.2.5 shall apply.

See Article C10.7.2.5.

10.9.2.6—Lateral Squeeze**C10.9.2.6**

The provisions of Article 10.7.2.6 shall apply.

See Article C10.7.2.6.

10.9.3—Strength Limit State Design**10.9.3.1—General****C10.9.3.1**

For strength limit state design, the following shall be determined:

- loads and performance requirements;
- micropile dimensions and nominal axial micropile resistance;
- size and configuration of the micropile group to provide adequate foundation support;
- estimated micropile length to be used in the construction contract documents to provide a basis for bidding;

- a minimum micropile penetration, if required, for the particular site conditions and loading, determined based on the maximum (deepest) penetration needed to meet all of the applicable requirements identified in Article 10.7.6; and
- the nominal structural resistance of the micropile and/or micropile group.

A minimum micropile penetration should only be specified if needed to insure that uplift, lateral stability, depth to resist drag load, depth to resist scour, and depth for structural lateral resistance are met for the strength limit state, in addition to similar requirements for the service and extreme event limit states. See Article C10.7.6 for additional details.

Punching of micropiles through strong soil into a weaker layer is not likely for micropiles designed for a resistance by bond transfer only.

10.9.3.2—Groundwater Effects and Buoyancy

The provisions of Article 10.7.3.5 shall apply.

C10.9.3.2

See Article C10.7.3.5.

10.9.3.3—Scour

The provisions of Article 10.7.3.6 shall apply.

C10.9.3.3

See Article C10.7.3.6.

10.9.3.4—Drag Load

The provisions of Article 10.7.3.7 shall apply.

C10.9.3.4

See Article C10.7.3.7.

10.9.3.5—Nominal Axial Compression Resistance of a Single Micropile

10.9.3.5.1—General

Micropiles shall be designed to resist failure of the bonded length in soil and rock, or for micropiles bearing on rock, failure of the rock at the micropile tip.

The factored resistance of a micropile, R_R , shall be taken as:

$$R_R = \phi R_n = \phi_{qp} R_p + \phi_{qs} R_s \quad (10.9.3.5.1-1)$$

in which:

$$R_p = q_p A_p \quad (10.9.3.5.1-2)$$

$$R_s = q_s A_s \quad (10.9.3.5.1-3)$$

where:

- ϕ = resistance factor (dim)
- R_n = nominal sliding resistance against failure by sliding (kips)
- R_p = nominal tip resistance (kips)
- R_s = nominal grout-to-ground bond resistance (kips)
- ϕ_{qp} = resistance factor for tip resistance, specified in Table 10.5.5.2.5-1
- ϕ_{qs} = resistance factor for grout-to-ground bond resistance, specified in Table 10.5.5.2.5-1
- q_p = unit tip resistance (ksf)

Micropiles are typically designed based on bond into soil and rock neglecting tip resistance due to their relatively small diameter and high grout-to-ground bond resistance. Tip resistance may be considered for micropiles bearing on hard rock although the axial capacity for this case is often controlled by the structural resistance of the micropile.

Both the tip and bond resistances develop in response to foundation displacement. The maximum values of each are unlikely to occur at the same displacement. The bond resistance is typically fully mobilized at displacements of about 0.1 to 0.4 in. The tip capacity, however, is mobilized after the micropile settles about six percent of its diameter (Jeon and Kulhawy, 2001), and is generally neglected in the design of micropiles in soil.

The methods for estimating micropile axial resistance provided in this article should be used. Micropile strength limit state resistance methods not specifically addressed in this Article for which adequate successful regional or national experience is available may be used, provided adequate information and experience is also available to develop appropriate resistance factors.

q_s = unit grout-to-ground bond resistance (ksf)
 A_p = area of micropile tip (ft²)
 A_s = area of grout-to-ground bond surface (ft²)

For final design, micropile resistance shall be verified through the performance of micropile load tests as described in Article 10.9.3.5.4. The resistance factors for micropiles shall be taken as specified in Table 10.5.5.2.5-1.

10.9.3.5.2—Estimation of Grout-to-Ground Bond Resistance

The nominal grout-to-ground bond resistance over the bonded length of a micropile, R_s , in kips shall be taken as:

$$R_s = \pi d_b \alpha_b L_b \quad (10.9.3.5.2-1)$$

where:

d_b = diameter of micropile drill hole through bonded length (ft)
 α_b = nominal micropile grout-to-ground bond strength (ksf)
 L_b = micropile bonded length (ft)

For final design, micropile capacity shall be verified through the performance of micropile load tests as described in Article 10.9.3.5.4.

C10.9.3.5.2

The value of nominal unit grout-to-ground bond strength, either estimated empirically or determined through load testing, is typically taken as the average value over the entire bond length.

Micropile grout-to-ground bond strength is influenced by soil and rock conditions, method of micropile drilling and installation, and grouting pressure. The final micropile geotechnical design should be performed by a specialty contractor qualified to perform micropile design and construction. As a guide, Table C10.9.3.5.2-1 may be used to estimate the nominal (ultimate) unit grout-to-ground bond strength for Types A, B, C, D, and E micropiles bonded into soil and/or rock for preliminary design.

For preliminary design, the grout-to-ground bond resistance of micropiles may be based on the results of micropile load tests; estimated based on a review of geologic and boring data, soil and rock samples, laboratory testing, and previous experience; or estimated using published soil/rock-grout bond guidelines.

Table C10.9.3.5.2-1—Summary of Typical α_b Values (Grout-to-Ground Bond) for Preliminary Micropile Design (modified after Sabatini et al., 2005)

Soil/Rock Description	Typical Range of Grout-to-Ground Bond Nominal Resistance for Micropile Types ⁽¹⁾ (ksf)				
	Type A	Type B	Type C	Type D	Type E
Silt & Clay (some sand) (soft medium plastic)	0.7–1.4	0.7–2.0	0.7–2.5	0.7–3.0	0.7–2.0
Silt & Clay (some sand) (stiff, dense to very dense)	0.7–2.5	1.4–4.0	2.0–4.0	2.0–4.0	1.4–4.0
Sand (some silt) (fine, loose-medium dense)	1.4–3.0	1.4–4.0	2.0–4.0	2.0–5.0	1.4–5.0
Sand (some silt, gravel) (fine-coarse, medium-very dense)	2.0–4.5	2.5–7.5	3.0–7.5	3.0–8.0	2.5–7.5
Gravel (some sand) (medium-very dense)	2.0–5.5	2.5–7.5	3.0–7.5	3.0–8.0	2.5–7.5
Glacial Till (silt, sand, gravel) (medium-very dense, cemented)	2.0–4.0	2.0–6.5	2.5–6.5	2.5–7.0	2.0–6.5
Soft Shales (fresh-moderate fracturing, little to no weathering)	4.3–11.5	N/A	N/A	N/A	N/A
Slates and Hard Shales (fresh- moderate fracturing, little to no weathering)	10.8–28.8	N/A	N/A	N/A	N/A
Limestone (fresh-moderate fracturing, little to no weathering)	21.6–43.2	N/A	N/A	N/A	N/A
Sandstone (fresh-moderate fracturing, little to no weathering)	10.8–36.0	N/A	N/A	N/A	N/A
Granite and Basalt (fresh-moderate fracturing, little to no weathering)	28.8–87.7	N/A	N/A	N/A	N/A

⁽¹⁾ Refer to Article 10.9.1 for description of micropile types.

10.9.3.5.3—Estimation of Micropile Tip Resistance in Rock

The methods used for design of micropiles bearing on rock shall consider the presence, orientation, and condition of discontinuities, weathering profiles, and other similar profiles as they apply at a particular site. The designer shall judge the competency of a rock mass in accordance with the provisions of Article 10.4.6.4.

For micropiles founded on competent rock, tip resistance may be estimated in accordance with the provisions of Article 10.8.3.5.4c.

C10.9.3.5.3

Micropiles are generally designed based on bond into rock rather than tip resistance. Tip resistance is generally considered only for micropiles bearing on competent rock.

For micropiles founded on competent rock, the rock is usually so sound that the structural capacity will govern the design.

Weak rock includes some shales and mudstones or poor-quality weathered rocks. The term “weak” has no generally accepted, quantitative definition; therefore, judgment and experience are required to make this determination.

10.9.3.5.4—Micropile Load Test

The load test shall follow the procedures specified in ASTM D1143 for compression and ASTM D3689 for tension. The loading procedure should follow the Quick-Load Test Method, unless detailed longer-term load-settlement data is needed, in which case the standard loading procedure should be used. Unless specified otherwise by the Engineer, the pile axial resistance shall be determined from the test data using the Davisson Method as presented in Article 10.7.3.8.2.

The number of load tests required to account for site variability shall be as specified in Article 10.5.5.2.3. The number of test micropiles required should be increased in nonuniform subsurface conditions.

In addition, proof tests loaded to the required factored load shall be performed on one pile per substructure unit or five percent of the piles, whichever is greater, unless specified otherwise by the Engineer.

The resistance factors for axial compressive resistance or axial uplift resistance shall be taken as specified in Table 10.5.5.2.5-1.

10.9.3.6—Resistance of Micropile Groups in Compression

Reduction in resistance from group effects shall be evaluated in accordance with the provisions of Article 10.7.3.9.

10.9.3.7—Nominal Uplift Resistance of a Single Micropile

Uplift resistance shall be evaluated when upward loads act on the micropiles. Micropiles subjected to uplift forces shall be investigated for resistance to pullout, for their structural strength, and for the strength of their connection to supported components.

10.9.3.8—Nominal Uplift Resistance of Micropile Groups

The provisions of Article 10.7.3.11 shall apply.

C10.9.3.5.4

See Article C10.8.3.5.6.

Load Tests on micropiles are performed to determine micropile installation characteristics, evaluate micropile capacity with depth, and establish micropile bond lengths.

During the performance of ASTM tests, the Contractor may perform several load cycles on the test micropile for diagnostic purposes.

Test micropiles may not be required where previous experience exists with the same micropile type and ultimate micropile capacity in similar subsurface conditions. However, load tests can differ even for apparently similar ground conditions. Therefore, care should be exercised in generalizing and extrapolating the test results to other locations.

Test micropiles are frequently planned for each substructure.

With approval of the Engineer, the number of load tests and proof tests can be reduced based on:

- previous micropile load tests in similar ground using similar methods, or
- site-specific tests showing much higher than required factored resistance or consistent proof test.

C10.9.3.6

See Article C10.7.3.9.

C10.9.3.7

Resistance factors in Article 10.5.5.2.5 assume a tension load test is performed. In the event that tension load tests are not performed, the resistance factor for presumptive values may be used or the tension resistance estimated as 50 percent of the compression resistance.

C10.9.3.8

Group uplift resistance in rock should consider the depth of soil overburden, rock discontinuity spacing and condition, and rock mass shear strength, as well as bond between micropiles and rock.

10.9.3.9—Nominal Horizontal Resistance of Micropiles and Micropile Groups

The provisions of Article 10.7.3.12 apply.

The design of horizontally loaded micropiles shall account for the effects of interaction between the micropiles and ground, including the number and spacing of micropiles in the group.

For micropiles used in groups, the micropile head shall be embedded into the cap and the degree of fixity shall be considered in the design.

10.9.3.10—Structural Resistance

10.9.3.10.1—General

The structural design of micropiles shall be in accordance with the provisions of Section 5 for the design of reinforced concrete and Section 6 for the design of steel.

The cased and uncased length of each micropile shall be designed to resist the forces distributed to the micropile based on the micropile inclination and spacing.

The resistance factors for structural design shall be as specified in Table 10.5.5.2.5-2.

10.9.3.10.2—Axial Compressive Resistance

The upper cased section of a micropile subjected to compression loading shall be designed structurally to support the full factored load on the micropile. The lower uncased section of a micropile subjected to compression loading shall be designed structurally to support the maximum full factored load on the micropile less the load transferred to the surrounding ground from the cased portion of the pile in the plunge length (if used), as described in Article 10.9.3.10.4.

For micropiles extending through a weak upper soil layer, extending above ground, subject to scour, extending through mines/caves, or extending through soil that may liquefy, the effect of any laterally unsupported length shall be considered in the determination of axial compression resistance.

The factored structural resistance of a micropile to axial compression loading, R_C , in kips may be taken as:

$$R_C = \phi_C R_n \quad (10.9.3.10.2-1)$$

where:

ϕ_C = resistance factor, specified in Table 10.5.5.2.5-2 for structural resistance of micropiles in axial compression

R_n = nominal axial compression resistance of micropile specified in Articles 10.9.3.10.2a and 10.9.3.10.2b (kips)

C10.9.3.9

See Article C10.7.3.12.

C10.9.3.10.1

Articles 5.8.2.4, 5.6.4, 5.6.6, 5.12.9, and 6.15 provide specific provisions applicable to design of concrete and steel micropiles.

The design of micropiles supporting axial compression load only requires an allowance for unintended eccentricity. This has been accounted for by use of the equations in Article 5.6.4.4 for reinforced concrete columns that already contain an eccentricity allowance.

10.9.3.10.3—Axial Tension Resistance

The upper cased section of a micropile subjected to tension loading shall be designed structurally to support the full factored load on the micropile. The lower uncased section of a micropile subjected to tension loading shall be designed structurally to support the maximum full factored load on the micropile less the load transferred to the surrounding ground from the cased portion of the micropile in the plunge length, as described in Article 10.9.3.10.4.

The factored structural resistance of a micropile subjected to tension, R_T , may be taken as:

$$R_T = \phi_T R_n \quad (10.9.3.10.3-1)$$

where:

ϕ_T = resistance factor, specified in Table 10.5.5.2.5-2 for structural resistance of a micropile subjected to tension loading (dim)

R_n = nominal axial tension resistance of micropile specified in Articles 10.9.3.10.3a and 10.9.3.10.3b

10.9.3.10.3a—Cased Length

The factored structural resistance of the upper cased length of a micropile subjected to tension loading, R_{TC} , in kips may be taken as:

$$R_{TC} = \phi_{TC} R_n \quad (10.9.3.10.3a-1)$$

for which:

$$R_n = f_y (A_b + A_{ct}) \quad (10.9.3.10.3a-2)$$

where:

ϕ_{TC} = resistance factor, specified in Table 10.5.5.2.5-2 for structural resistance of the cased section of a micropile subjected to tension loading (dim)

f_y = specified minimum yield strength of reinforcement bar or steel casing, whichever is less (ksi)

A_b = cross-sectional area of steel reinforcing bar (in.²)

A_{ct} = cross-sectional area of steel casing considering reduction for threads (in.²)

10.9.3.10.3b—Uncased Length

The factored structural resistance of the lower uncased length of a micropile subjected to tension loading, R_{TU} , in kips may be taken as:

$$R_{TU} = \phi_{TU} R_n \quad (10.9.3.10.3b-1)$$

for which:

$$R_n = f_y A_b \quad (10.9.3.10.3b-2)$$

C10.9.3.10.3a

The design compressive stress in the steel is limited to the stress at which the strain equals 0.003 to maintain compatibility with the strain in the grout.

where:

- ϕ_{TU} = resistance factor, specified in Table 10.5.5.2.5-2 for structural resistance of the uncased section of a micropile subjected to tension loading (dim)
- f_y = specified minimum yield strength of reinforcement bar (kip)
- A_b = cross-sectional area of steel reinforcing bar (in.²)

10.9.3.10.4—Plunge Length Transfer Load

The factored axial load transferred to the ground through the plunge length of the cased portion of a micropile, P_t , in kips, may be taken as:

$$P_t = \phi \left[\pi d_b \alpha_b L_p \right] \quad (10.9.3.10.4-1)$$

where:

- ϕ = resistance factor, specified in Table 10.5.5.2.5-1 for geotechnical bearing or uplift resistance, as appropriate, of a single micropile
- d_b = diameter of micropile drill hole through bonded length (ft)
- α_b = nominal micropile grout-to-ground bond strength (ksf)
- L_p = micropile casing plunge length (ft)

If load transfer through the plunge length of the cased portion of a micropile is considered to reduce the load on the lower uncased portion of the micropile, the factored axial load on the uncased portion of the micropile in compression or tension, P_u , in kips, may be taken as:

$$P_u = Q - P_t \quad (10.9.3.10.4-2)$$

where:

- Q = $\sum \eta_i \gamma_i Q_i$
- = total factored axial load on micropile (kips)
- P_t = factored axial load transferred to the ground through the plunge length of the cased portion of a micropile from Eq. 10.9.3.10.4-1 (kips)

10.9.3.10.5—Grout-to-Steel Bond

Casing-to-grout bond shall be checked and reinforcement bar development length shall be checked in accordance with the provisions of Section 5.

C10.9.3.10.4

An optional procedure for construction of a composite reinforced micropile includes insertion of the pile casing into the top of the grouted bond zone to effect a transition between the upper cased portion to the lower uncased portion of a micropile. The length of casing inserted into the bond zone by the plunge length is shown in Figure C10.9.1-1. As a result, a portion of the factored axial load on a micropile is transferred to the surrounding ground by the cased portion of the pile, reducing the load that must be supported by the weaker uncased portion of the pile. The reduction in load applied to the uncased length is termed the transfer load P_t .

C10.9.3.10.5

Grout-to-steel bond does not typically govern micropile design, except for overlap of reinforcing bars into upper casing.

The bond between the cement grout and the reinforcing steel is the mechanism for transfer of the pile load from the reinforcing steel to the ground. Typical ultimate bond values range from 0.15 to 0.25 ksi for smooth bars and pipe, and 0.30 to 0.50 ksi for deformed bars (Armour et al., 2000). Refer to Section 5 for bar development requirements.

As is the case with any reinforcement, the surface condition will affect the attainable bond. A film of rust

may be beneficial, but the presence of loose debris or lubricant or paint is not desirable. Normal methods for the handling and storage of reinforcing bars apply to micropile construction. For the permanent casing that is also used to drill the hole, cleaning of the casing surface can occur during drilling, particularly in granular soils.

10.9.3.10.6—Buckling and Lateral Stability

The provisions of Article 10.7.3.13.4 shall apply.

10.9.3.10.7—Reinforcement into Superstructure

Sufficient reinforcement shall be provided at the junction of the micropile with the micropile footing or column to make a suitable connection. The embedment of the reinforcement into the cap shall comply with the provision for cast-in-place piles in Section 5.

C10.9.3.10.7

Refer to Sabatini et al. (2005) for typical micropile to footing connection details.

10.9.4—Extreme Event Limit State

The provisions of Articles 10.5.5.3 and 10.7.4 shall apply.

C10.9.4

See Articles C10.5.5.3 and C10.7.4.

10.9.5—Corrosion and Deterioration

The provisions of Article 10.7.5 shall apply.

C10.9.5

Corrosion protection methods and design presented in Article C10.7.5 apply to micropiles as well. In addition, other micropile specific design options including plastic encapsulation of central reinforcing bars is provided in Sabatini (2005).

APPENDIX A10—SEISMIC ANALYSIS AND DESIGN OF FOUNDATIONS

A10.1—INVESTIGATION

Slope instability, liquefaction, fill settlement, and increases in lateral earth pressure have often been major factors contributing to bridge damage in earthquakes. These earthquake hazards may be significant design factors for peak earthquake accelerations in excess of 0.1 g and should form part of a site-specific investigation if the site conditions and the associated acceleration levels and design concepts suggest that such hazards may be of importance.

A10.2—FOUNDATION DESIGN

The commonly-accepted practice for the seismic design of foundations is to utilize a pseudo-static approach, where earthquake-induced foundation loads are determined from the reaction forces and moments necessary for structural equilibrium. Although traditional bearing capacity design approaches are also applied, with appropriate capacity reduction factors if a margin of safety against “failure” is desired, a number of factors associated with the dynamic nature of earthquake loading should always be borne in mind.

Under cyclic loading at earthquake frequencies, the strength capable of being mobilized by many soils is greater than the static strength. For unsaturated cohesionless soils, the increase may be about ten percent, whereas for cohesive soils, a 50 percent increase could occur. However, for softer saturated clays and saturated sands, the potential for strength and stiffness degradation under repeated cycles of loading must also be recognized. For bridges classified as Zone 2, the use of static soil strengths for evaluating ultimate foundation capacity provides a small implicit measure of safety and, in most cases, strength and stiffness degradation under repeated loading will not be a problem because of the smaller magnitudes of seismic events. However, for bridges classified as Zones 3 and 4, some attention should be given to the potential for stiffness and strength degradation of site soils when evaluating ultimate foundation capacity for seismic design.

As earthquake loading is transient in nature, “failure” of soil for a short time during a cycle of loading may not be significant. Of perhaps greater concern is the magnitude of the cyclic foundation displacement or rotation associated with soil yield, as this could have a significant influence on structural displacements or bending moments and shear distributions in columns and other members.

As foundation compliance influences the distribution of forces or moments in a structure and affects computation of the natural period, equivalent stiffness factors for foundation systems are often required. In many cases, use is made of various analytical solutions that are available for footings or piles where it is assumed that soil behaves in an elastic medium. In using these formulae, it should be recognized that equivalent elastic moduli for soils are a function of strain amplitude, and for seismic loads modulus values could be significantly less than those appropriate for low levels of seismic loading. Variation of shear modulus with shearing strain amplitude in the case of sands is shown in Figure A10.2-1. Additional discussion of this topic can be found in the *AASHTO Guide Specifications for LRFD Seismic Bridge Design*.

Figure A10.2-2—Lateral Loading of Piles in Sand Using API Criteria

The influence of group action on pile stiffness is a somewhat controversial subject. Solutions based on elastic theory can be misleading where yield near the pile head occurs. Experimental evidence tends to suggest that group action is not significant for pile spacings greater than $4d$ to $6d$.

For batter pile systems, the computation of lateral pile stiffness is complicated by the stiffness of the piles in axial compression and tension. It is also important to recognize that bending deformations in batter pile groups may generate high reaction forces on the pile cap.

It should be noted that although battered piles are economically attractive for resisting horizontal loads, such piles are very rigid in the lateral direction if arranged so that only axial loads are induced. Hence, large relative lateral displacements of the more flexible surrounding soil may occur during the free-field earthquake response of the site (particularly if large changes in soil stiffness occur over the pile length), and these relative displacements may in turn induce high pile bending moments. For this reason, more flexible vertical pipe systems where lateral load is resisted by bending near the pile heads are recommended. However, such pile systems must be designed to be ductile because large lateral displacements may be necessary to resist the lateral load. A compromise design using battered piles spaced some distance apart may provide a system that has the benefits of limited flexibility and the economy of axial load resistance to lateral load.

Soil-Pile Interaction—The use of pile stiffness characteristics to determine earthquake-induced pile bending moments based on a pseudo-static approach assumes that moments are induced only by lateral loads arising from inertial effects on the bridge structure. However, it must be remembered that the inertial loads are generated by interaction of the free-field earthquake ground motion with the piles and that the free-field displacements themselves can influence bending moments. This is illustrated in an idealized manner in Figure A10.2-3. The free-field earthquake displacement time histories provide input into the lateral resistance interface elements, which in turn transfer motion to the pile. Near the pile heads, bending moments will be dominated by the lateral interaction loads generated by inertial effects on the bridge structure. At greater depth (e.g., greater than $10d$), where soil stiffness progressively increases with respect to pile stiffness, the pile will be constrained to deform in a manner similar to that of the free field, and pile bending moments become a function of the curvatures induced by free-field displacements.

Figure A10.2-3—Mechanism of Soil-Pile Interaction during Seismic Loading

To illustrate the nature of free-field displacements, reference is made to Figure A10.2-4, which represents a 200-ft deep cohesionless soil profile subjected to the El Centro earthquake. The free-field response was determined using a nonlinear, one-dimensional response analysis. From the displacement profiles shown at specific times, curvatures can be computed and pile bending moments calculated if it is assumed that the pile is constrained to displace in phase with the free-field response.

Figure A10.2-4—Typical Earthquake Displacement Profiles

Large curvatures could develop at interfaces between soft and rigid soils and, clearly, in such cases emphasis should be placed on using flexible ductile piles. Margason (1979) suggests that curvatures of up to $6 \times 10^{-4} \text{ in.}^{-1}$ could be induced by strong earthquakes, but these should pose no problem to well-designed steel or prestressed concrete piles.

Studies incorporating the complete soil–pile structure interaction system, as presented in Figure A10.2-3, have been described by Penzien (1970) for a bridge piling system in deep soft clay. A similar but somewhat simpler soil–pile structure interaction system (SPASM) to that used by Penzien has been described by Matlock et al. (1978). The model used is, in effect, a dynamic version of the previously mentioned BMCOL program.

A10.3—SPECIAL PILE REQUIREMENTS

The uncertainties of ground and bridge response characteristics lead to the desirability of providing tolerant pile and foundation systems. Toughness under induced curvature and shears is required, and hence piles such as steel H-sections and concrete filled steel-cased piles are favored for highly seismic areas. Unreinforced concrete piles are brittle in nature, so nominal longitudinal reinforcing is specified to reduce this hazard. The reinforcing steel should be extended into the footing to tie elements together and to assist in load transfer from the pile to the pile cap.

Experience has shown that reinforced concrete piles tend to hinge or shatter immediately below the pile cap. Hence, tie spacing is reduced in this area so that the concrete is better confined. Driven precast piles should be constructed with considerable spiral confining steel to ensure good shear strength and tolerance of yield curvatures should these be imparted by the soil or structural response. Clearly, it is desirable to ensure that piles do not fail below ground level and that flexural yielding in the columns is forced to occur above ground level. The additional pile design requirements imposed on piles for bridges classified as Zones 3 and 4, for which earthquake loading is more severe, reflect a design philosophy aimed at minimizing below-ground damage that is not easily inspected following a major earthquake.

SECTION 11

WALLS, ABUTMENTS, AND PIERS

Commentary is opposite the text it annotates.

11.1—SCOPE

This Section provides requirements for design of abutments and walls. Conventional retaining walls, nongravity cantilevered walls, anchored walls, mechanically stabilized earth (MSE) walls, prefabricated modular walls, and soil nail walls are considered.

11.2—DEFINITIONS

Abutment—A structure that supports the end of a bridge span, and provides lateral support for fill material on which the roadway rests immediately adjacent to the bridge. In practice, different types of abutments may be used. These include:

- **Stub Abutment**—Stub abutments are located at or near the top of approach fills, with a backwall depth sufficient to accommodate the structure depth and bearings which sit on the bearing seat.
- **Partial-Depth Abutment**—Partial-depth abutments are located approximately at mid-depth of the front slope of the approach embankment. The higher backwall and wingwalls may retain fill material, or the embankment slope may continue behind the backwall. In the latter case, a structural approach slab or end span design must bridge the space over the fill slope, and curtain walls are provided to close off the open area. Inspection access should be provided for this situation.
- **Full-Depth Abutment**—Full-depth abutments are located at the approximate front toe of the approach embankment, restricting the opening under the structure.
- **Integral Abutment**—Integral abutments are rigidly attached to the superstructure and are supported on a spread footing or a deep foundation capable of permitting necessary horizontal movements.

Anchored Wall—An earth retaining system typically composed of the same elements as nongravity cantilevered walls, and that derive additional lateral resistance from one or more tiers of anchors.

Geogrid—A geosynthetic formed by a regular network of integrally connected elements with apertures greater than 0.25 in. to allow interlocking with surrounding soil, rock, earth, and other surrounding materials to function primarily as reinforcement.

Geostrip—Polymeric material in the form of a strip (also sometimes called a polymer strap) of width not more than 8.0 in., used in contact with soil or other materials in geotechnical and civil engineering applications, or both.

Geotextile—A permeable geosynthetic comprised solely of textiles.

Mechanically Stabilized Earth (MSE) Wall—A soil-retaining system, employing either strip- or grid-type, metallic, or polymeric tensile reinforcements in the soil mass, and a facing element that is either vertical or nearly vertical.

Nongravity Cantilever Wall—A soil-retaining system that derives lateral resistance through embedment of vertical wall elements and supports retained soil with facing elements. Vertical wall elements may consist of discrete elements, e.g., piles, drilled shafts, or auger-cast piles spanned by a structural facing, e.g., lagging, panels, or shotcrete. Alternatively, the vertical wall elements and facing may be continuous, e.g., sheet piles, diaphragm wall panels, tangent-piles, or tangent drilled shafts.

Pier—Part of a bridge structure that provides intermediate support to the superstructure. Different types of piers may be used. These include:

- **Solid Wall Piers**—Solid wall piers are designed as columns for forces and moments acting about the weak axis and as piers for those acting about the strong axis. They may be pinned, fixed, or free at the top, and are conventionally fixed at the base. Short, stubby types are often pinned at the base to eliminate the high moments which would develop due to fixity. Earlier, more massive designs were considered gravity types.

- *Double Wall Piers*—Double wall piers consist of two separate walls, spaced in the direction of traffic, to provide support at the continuous soffit of concrete box superstructure sections. These walls are integral with the superstructure and must also be designed for the superstructure moments which develop from live loads and erection conditions.
- *Bent Piers*—Bent-type piers consist of two or more transversely spaced columns of various solid cross-sections, and these types are designed for frame action relative to forces acting about the strong axis of the pier. They are usually fixed at the base of the pier and are either integral with the superstructure or with a pier cap at the top. The columns may be supported on a spread- or pile-supported footing, or a solid wall shaft, or they may be extensions of the piles or shaft above the ground line.
- *Single-Column Piers*—Single-column piers, often referred to as “T” or “Hammerhead” piers, are usually supported at the base by a spread-, drilled shaft- or pile-supported footing, and may be either integral with, or provide independent support for, the superstructure. Their cross-section can be of various shapes and the column can be prismatic or flared to form the pier cap or to blend with the sectional configuration of the superstructure cross-section. This type of pier can avoid the complexities of skewed supports if integrally framed into the superstructure and their appearance reduces the massiveness often associated with superstructures.
- *Tubular Piers*—A hollow core section which may be of steel, reinforced concrete, or prestressed concrete, of such cross-section to support the forces and moments acting on the elements. Because of their vulnerability to lateral loadings, tubular piers shall be of sufficient wall thickness to sustain the forces and moments for all loading situations as are appropriate. Prismatic configurations may be sectionally precast or prestressed as erected.

Prefabricated Modular Wall—A soil-retaining system employing interlocking soil-filled timber, reinforced concrete, or steel modules or bins to resist earth pressures by acting as gravity retaining walls.

Rigid Gravity and Semi-Gravity (Conventional) Retaining Wall—A structure that provides lateral support for a mass of soil and that owes its stability primarily to its own weight and to the weight of any soil located directly above its base.

In practice, different types of rigid gravity and semi-gravity retaining walls may be used. These include:

- A *gravity wall* depends entirely on the weight of the stone or concrete masonry and of any soil resting on the masonry for its stability. Only a nominal amount of steel is placed near the exposed faces to prevent surface cracking due to temperature changes.
- A *semi-gravity wall* is somewhat more slender than a gravity wall and requires reinforcement consisting of vertical bars along the inner face and dowels continuing into the footing. It is provided with temperature steel near the exposed face.
- A *cantilever wall* consists of a concrete stem and a concrete base slab, both of which are relatively thin and fully reinforced to resist the moments and shears to which they are subjected.
- A *counterfort wall* consists of a thin concrete face slab, usually vertical, supported at intervals on the inner side by vertical slabs or counterforts that meet the face slab at right angles. Both the face slab and the counterforts are connected to a base slab, and the space above the base slab and between the counterforts is backfilled with soil. All the slabs are fully reinforced.
- A *soil nail wall* is an earth-retaining system containing passive reinforcing elements that are drilled and grouted sub-horizontally in the ground.

11.3—NOTATION

A_c	=	cross-sectional area of reinforcement unit (in. ²) (11.10.6.4.3a)
A_H	=	cross-sectional area of the head of a stud (in. ²) (11.12.6.2.4)
A'_{HN}	=	equivalent cross-sectional area at the head in the vertical direction (in. ²) (11.12.6.2.2)
A_S	=	S_a , at a period of zero seconds; cross-sectional area of the shaft of a headed stud (in. ²) (11.6.5.2.1) (11.6.5.3) (11.12.6.2.4) (A11.3.2) (A11.5.1) (A11.5.2)
A_t	=	cross-sectional area of soil nail tendon (in. ²) (11.12.6.1)
A'_{VN}	=	equivalent cross-sectional area at the head in the horizontal direction (in. ²) (11.12.6.2.2)
